Key Points:

• Four remote sensin	g ET model	s were evaluated	using data fro	om 25 flux towers in
South America				

- GLEAM and PT-JPL provided a significantly greater number of daily outputs
- Comparisons with flux tower-based ET showed that GLEAM and PT-JPL produced higher correlations whereas RMSE was similar for all models
 - No model outperformed the other for all biomes, climates or land uses

Corresponding author: Davi Diniz Melo, melo.dcd@gmail.com

48 Abstract

Many remote sensing-based evapotranspiration (RSBET) algorithms have been proposed 49 in the past decades and evaluated using flux tower data, mainly over North America and 50 Europe. Model evaluation across South America has been done locally or using only a 51 single algorithm at a time. Here, we provide the first evaluation of multiple RSBET mod-52 els, at a daily scale, across a wide variety of biomes, climate zones, and land uses in South 53 America. We used meteorological data from 25 flux towers to force four RSBET mod-54 els: Priestley–Taylor Jet Propulsion Laboratory (PT-JPL), Global Land Evaporation Am-55 sterdam Model (GLEAM), Penman–Monteith Mu model (PM-MOD), and Penman–Monteith 56 Nagler model (PM-VI). ET was predicted satisfactorily by all four models, with corre-57 lations consistently higher $(R^2 > 0.6)$ for GLEAM and PT-JPL, and PM-MOD and 58 PM-VI presenting overall better responses in terms of percent bias (-10 < PBIAS <59 10%). As for PM-VI, this outcome is expected, given that the model requires calibra-60 tion with local data. Model skill seems to be unrelated to land-use but instead presented 61 some dependency on biome and climate, with the models producing the best results for 62 wet to moderately wet environments. Our findings show the suitability of individual mod-63 els for a number of combinations of land cover types, biomes, and climates. At the same 64 time, no model outperformed the other for all conditions, which emphasizes the need 65 for adapting individual algorithms to take into account intrinsic characteristics of climates 66 and ecosystems in South America. 67

68 1 Introduction

Land evaporation, or evapotranspiration (ET), is the phenomenon by which wa-69 ter is converted from a liquid into its vapor phase over land. It plays a significant role 70 in the modulation of global climate feedbacks being a key driver of the Earth's carbon, 71 energy, and water cycles at local, regional, and global scales (Cao et al., 2010; Tong et 72 al., 2017; Khosa et al., 2019; Valle Júnior et al., 2020; de Oliveira et al., 2021). In situ 73 ET measurements can be obtained from micro-meteorological methods (e.g., eddy co-74 variance, scintillometry, or Bowen ratio method) and those derived from the soil water 75 balance (e.g., directly using lysimeters, or from changes in profile soil moisture content 76 obtained gravimetrically, from neutron probes, or capacitance-based soil water monitor-77 ing equipment). Besides, plant physiological techniques such as sap flow methods, pro-78 vide direct estimates of transpiration (Verhoef & Campbell, 2006; Allen et al., 2011; Fisher 79 et al., 2011), but only the micro-meteorological methods provide ET data at the field 80 to landscape (e.g., scintillometry) scale. Over the past three decades, eddy covariance 81 (EC) systems have become the state-of-the-art and standard *in situ* method to quan-82 tify land surface energy and mass fluxes for different types of ecosystems (Restrepo-Coupe 83 et al., 2013; Rodrigues et al., 2016; Campos et al., 2019; X. Wang et al., 2020). However, 84 these techniques estimate fluxes for areas of relatively limited spatial dimensions ($\sim 1 \text{ km}^2$) 85 depending on the heterogeneity of the landscape), and they are affected by specific lo-86 cal conditions, such as the occurrence of advection across sharp contrasts in vegetation 87 and/or irrigation conditions, and those caused by topographic features, such as cold air 88 drainage for sloping terrain (Allen et al., 2011; Rwasoka et al., 2011; Mutti et al., 2019; 89 Rahimzadegan & Janani, 2019; Mauder et al., 2020). 90

During the 1990s and 2000s, remote sensing based ET (RSBET) algorithms, us-91 ing information from visible, near-infrared, and thermal infrared bands, were developed, 92 such as the Surface Energy Balance Algorithms for Land (SEBAL, (Bastiaanssen et al., 93 1998)), Simplified Surface Energy Balance Index (S-SEBI, Roerink et al. (2000)), Sur-94 face Balance Energy System (SEBS, Su (2002)), Simplified Surface Energy Balance (SSEB, 95 Senay et al. (2007)), and Two-Source Energy Balance Model (TSEB, Norman et al. (1995); 96 Kustas and Norman (1999)). These algorithms were developed for sub-regional appli-97 cations, with a focus on irrigation or water resources management. Over South Amer-98 ica, their predictive skills have been assessed quite extensively, mostly for irrigated crop-99

land (Teixeira et al., 2009; Paiva et al., 2011; Poblete-Echeverría & Ortega-Farias, 2012;
Bezerra et al., 2013, 2015; Olivera-Guerra et al., 2017; Lopes et al., 2019; Mutti et al.,
2019). Studies show that these models perform well when compared to field observations
of *ET* (Teixeira et al., 2009; Poblete-Echeverría & Ortega-Farias, 2012).

Since the late 2000s, algorithms such as PT-JPL (Fisher et al., 2008), PM-MOD
(Mu et al., 2007, 2011), and GLEAM (Miralles et al., 2011; Martens et al., 2017) focused
on the use of satellite-derived observations to create spatially coherent global *ET* estimates (Fisher et al., 2017). PT-JPL is at the core of the ECOSTRESS mission (Fisher
et al., 2020), while PM-MOD is central to the global terrestrial MODIS *ET* product (MOD16).
GLEAM is used for the annual State of the Climate report since 2015 (Blunden & Arndt, 2020).

Using flux tower data, previous studies conducted in South America evaluated GLEAM 111 and MOD16 (Ruhoff et al., 2013; Moreira et al., 2019; Paca et al., 2019). However, these 112 studies validated off-the-shelf ET datasets generated by these models, not the models 113 themselves. Since such ET products are not produced using a common dataset of me-114 teorological variables, a comparative evaluation cannot be made in terms of model struc-115 ture. Rather, different model skills would be partially linked with the quality of the in-116 puts. A multi-site tropical study, over several continents, validating the PT-JPL model 117 at a regional scale on a monthly basis was presented by Fisher et al. (2009). However, 118 to the best of our knowledge, studies assessing the daily predictive skills have only been 119 conducted at the local scale (Teixeira et al., 2009, 2013; Miranda et al., 2017; B. S. Oliveira 120 et al., 2018; V. d. A. Souza et al., 2019). 121

A major challenge to verify the results of these methods is the scarcity of ground-122 based observations, due to the uneven spatio-temporal distribution of the ET monitor-123 ing efforts. As a result, remote sensing ET methods are typically evaluated or param-124 eterized using sites located only in North America, Europe (Ershadi et al., 2014; McCabe 125 et al., 2016; Michel et al., 2016; Xu et al., 2019), Australia (Martens et al., 2016) and 126 East Asia (Jang et al., 2013; Chang et al., 2018; Khan et al., 2018; Li et al., 2019). For 127 example, Mu et al. (2011) proposed improvements to the PM-MOD ET global algorithm 128 (Mu et al., 2007), based on comparisons with ET measurements from 46 AmeriFlux sites, 129 45 of them located in USA and Canada. Martens et al. (2017) evaluated the GLEAM 130 algorithm with 91 worldwide FLUXNET sites; however, ~ 65 were located in the USA 131 and in Europe. Therefore, these models might not satisfactorily represent ET in sparsely 132 sampled regions with very different climate conditions such as South America, despite 133 this continent representing ca. 12% of the total Earth's terrestrial area. 134

South America spans two hemispheres, and four major climate zones, from near 135 the equator to sub-Antarctic regions, which makes it a geographically unique continent 136 (Goymer, 2017; Trajano, 2019). Biomes in this continent range from tropical to decid-137 uous forests, and contain ecoregions with high sensitivity to variability in water (e.g., 138 the Caatinga and Humid Pampas) and energy availability (e.g. the Amazon, Valdivian 139 temperate and Magellanic subpolar forests) (Seddon et al., 2016). Also, five out of six 140 of the terrestrial biomes not included in satellite-based ET algorithm evaluations at a 141 global scale are found in South America (see Section 2.1). Thus, the evaluation of RS-142 BET methods for South America offers an opportunity to reduce the current research 143 gap, in particular at large spatial scales. 144

FLUXNET provides a common framework for the verification of ET algorithms. Nevertheless, the available sites in the FLUXNET2015 database are not evenly distributed around the world (Pastorello et al., 2020). Validating global models in South America is challenging, mainly because the data from ~90% of its FLUXNET registered sites are not readily available to the scientific community: less than 50% of South American AmeriFlux sites are available for direct access. Additionally, flux towers in woody savannas and evergreen broad-leaf forests account for nearly 65% of all Latin American FLUXNET sites while some of the biomes are not properly represented (Villarreal & Vargas, 2021).

The identification of scientific gaps and the proposed improvements are considered 153 a priority for the future development of ET assessment methods from remote sensing 154 (Fisher et al., 2017). Some of them include merging different ET-estimation methods, 155 and the identification of their sources of uncertainty (Fisher et al., 2017; Y. Zhang et al., 156 2017; Paca et al., 2019). Indeed, despite the recent developments of remote sensing ET157 methods, there are still challenges concerning the refinement of those algorithms to rem-158 edy the lack of information on specific surface characteristics and fluxes of undersam-159 pled climate zones and vegetation types. In this context, one of the main sources of un-160 certainty in global satellite-based ET estimates are the fractional vegetation cover and 161 net radiation (Ferguson et al., 2010; Vinukollu et al., 2011; Badgley et al., 2015) 162

We evaluated the predictive skills of four satellite-based ET models, designed for regional and continental scale applications, over South America. The main question we seek to answer is whether such models can be applied consistently to reliably capture ET in South America. Specific research questions include: (i) are the models capable of correctly estimating ET and its components? (ii) are the models predictive skills affected by climate, land cover type or biome?

¹⁶⁹ 2 Study area, data, and methods

170

171

2.1 South American biomes, flux tower-based ET and meteorological data

The study area encompasses five biomes (Table S1 in the Supporting Material –
SM): Tropical & Subtropical Moist Broadleaf Forests (TSMBF); Flooded Grasslands &
Savannas (FGS); Tropical & Subtropical Grasslands, Savannas & Shrublands (TSGSS);
Tropical & Subtropical Dry Broadleaf Forests (TSDBF) and Temperate Broadleaf & Mixed
Forests (TBMF) (Olson et al., 2001).

We used daily meteorological data from 25 flux tower sites located across various 177 South American biomes and land cover types to verify the predictive skill of the selected 178 RSBET models (Figure 1a, Table S2 in SM). The time period considered for analysis was 179 determined by the available time-series for each site (Figure S1 in SM). Further infor-180 mation about each biome is provided in SM. Ten sites are from FLUXNET (Pastorello 181 et al., 2020), AmeriFlux networks (Novick et al., 2018) and Large-Scale Biosphere-Atmosphere 182 Experiment in the Amazon (LBA) project (Saleska et al., 2013), while the remaining data 183 were obtained from the respective principal investigators. Concerning towers sites not 184 available in global networks, data handling included standard procedures to ensure qual-185 ity data, including: detection of spikes caused by changes in the footprint or imprecise 186 measurements; delay correction of H_2O/CO_2 in relation to the vertical wind component; 187 correction of coordinates (2D rotation); correction of spectral loss; conversion of the buoy-188 ancy flux to sensible heat flux, known as SND-corrections (Schotanus et al., 1983); sonic 189 virtual temperature correction; corrections for flux density fluctuations, known as WPL 190 corrections (Webb. et al., 1980); incorporated frequency response correction. Addition-191 ally, we performed due corrections with respect to reduction of wind velocity or turbu-192 lence increase caused by the shadow of the tower and the sensor. Details about proce-193 dures carried out for data processing and filtering to implement these corrections can 194 be found in Tonti et al. (2018); Holl et al. (2019); Campos et al. (2019); Cabral et al. (2020). 195 We also emphasize that those data have been widely used in previously scientific pub-196 lications (Rocha et al., 2009; Cabral et al., 2010, 2011; Restrepo-Coupe et al., 2013; Ro-197 drigues et al., 2016; Arruda et al., 2016; Silva et al., 2017; Marques et al., 2020). The 198 spatial patterns of mean annual precipitation (P), air temperature (T), and potential 199

evapotranspiration (*PET*) show that selected sites encompass a wide variety of climates

²⁰¹ (Figure 1b).

Figure 1. (a) Location of flux tower sites. Land cover types are indicated prior to tower names in the map: Croplands (CROP), Deciduous Needleaf Forest (DNF), Evergreen Broadleaf Forest (EBF), Grasslands (GRA), Mixed Forest (MF), Permanent Wetland (PW), and Woody Savanna (WS); Biome types (Olson et al., 2001) are indicated by shades of green, yellow and blue on the map (see legend): Tropical & Subtropical Moist Broadleaf Forests (TSMBF); Tropical & Subtropical Dry Broadleaf Forests (TSDBF); Temperate Broadleaf & Mixed Forests (TBMF); Tropical & Subtropical Grasslands, Savannas & Shrublands (TSGSS); Temperate Grasslands, Savannas & Shrublands (TGSS); Flooded Grasslands & Savannas (FGS); Montane Grasslands & Shrublands (MGS); Mediterranean Forests, Woodlands & Scrub (MFWS); Deserts & Xeric Shrublands (DXS); Climates across South America from selected representative sites are indicated by patterns on the map (see legend): Tropical savanna (Aw), Tropical monsoon (Am), Hot semi-arid (BSh), Cold semi-arid (BSk), Humid subtropical (Cfa), Temperate oceanic (Cfb), Drywinter subtropical highland (Cwb), Polar Tundra (Td) (Peel et al., 2007). (b) Gridded annual average (AVG) and standard deviation (SD) for air temperature (T), rainfall (P), and potential evapotranspiration (PET) across South America and the monitored sites (Harris et al., 2020).

The closure of the energy budget is rarely observed with flux tower measurements 202 (Wilson et al., 2002; Foken, 2008). Usually, the available energy flux (Rn-G) is greater 203 than (LE+H), where Rn is the net radiation, G is the soil heat flux, LE is the latent 204 heat flux and H is the sensible heat flux. The imbalances in the surface energy balance. 205 reported here as an energy balance ratio, EBR (i.e. (LE+H)/(Rn-G)), range from 206 0.73 to 1.16 (mean ~ 0.90) (Table S2, SM). It is paramount that only high-quality data 207 were used to run and assess the models. We computed daily EBR for each site and ex-208 cluded days with EBR ≤ 0.75 or ≥ 1.25 . Daily averages of meteorological variables were 209 calculated from 30-min or hourly data only when at least 80% of the records per day were 210 available. To obtain daytime and nighttime inputs for the MOD16 model (PM-MOD in 211 this paper), we considered only days with a minimum of twenty 30-min daytime records 212 and twenty during the night. As in Mu et al. (2011), the shortwave incoming radiation 213 $(Rgs \downarrow)$ was used to distinguish between daytime $(Rgs \downarrow > 10 \,\mathrm{W \, m^{-2}})$ and nighttime $(Rgs \downarrow < 10 \,\mathrm{W \, m^{-2}})$ 214 $10 \,\mathrm{W \, m^{-2}}$). Regarding the fluxes, we used quality-checked data that had not been gap-215 filled. Previous studies have shown that ET derived from the other energy balance fluxes, 216 i.e. LE = Rn - G - H, can agree well with eddy covariance ET and lysimeter data 217 (Amiro, 2009; Sánchez et al., 2019). Therefore, instead of using the EC-measured LE, 218 to represent ET, we derived LE from the equation above. Such validation approach (i.e. 219 comparing model ET with EB-derived LE, ET_{EB} has been adopted in previous stud-220 ies (Twine et al., 2000; Wilson et al., 2002; Stoy et al., 2013; Fisher et al., 2020). The 221 results of using the eddy covariance $ET(ET_{EC})$ instead can be found in the SM (see 222 Fig. S11-S13). 223

The quality control procedure described above was not adopted for the TF1, and 224 TF2 towers (see Figure 1a). At those sites, horizontal advection plays an important role 225 due to extreme weather variations throughout the year (Levy et al., 2020), such that the 226 energy balance closure cannot be diagnosed by EBR, as described above. For instance, 227 the SDF zone is known as an anticyclone pathway between the Pacific and Atlantic oceans, 228 and TF1 and TF2 are located in the extreme southern parts of Patagonia, a region char-229 acterized by strong winds. Thus, for TF1 and TF2 sites, we used ET derived from mea-230 sured LE. 231

2.2 Remote sensing-based vegetation indices

The required vegetation index (VI) to run PT-JPL, PM-MOD and PM-VI is the 233 Enhanced Vegetation Index (EVI). Vegetation Optical Depth (VOD) is used in GLEAM. 234 EVI was derived from the 16-day Level 3 Global product of the MODerate Resolution 235 Imaging Spectroradiometer (MODIS), aboard the Terra and Aqua satellites (Huete et 236 al., 2002). We used both MODIS VI products, i.e. MOD13Q1 (Terra) and MYD13Q1 237 (Aqua), at 250-m resolution, to derive daily composites of EVI. VOD was extracted 238 from the product described in Moesinger et al. (2020). Fisher et al. (2008) used the Soil 239 Adjusted Vegetation Index (SAVI) instead of EVI because the former does not require 240 the blue reflectance (0.45–0.51 μ m), however, the authors recognize that both indices are 241 very similar. As we are interested in assessing the ET models rather than the products 242 resulting from different forcing data, we used EVI in Fisher's model (PT-JPL). Leaf area 243 index (LAI) and other vegetation-related variables (e.g., fraction of Absorbed Photo-244 synthetically Active Radiation, f_{PAR}) are handled differently in each model. For exam-245 ple, in PT-JPL, LAI is obtained from total fractional vegetation cover, whereas in PM-246 MOD the 1-km MODIS LAI (MOD15) product is adopted. The original procedures to 247 obtain those variables were not changed here. The following treatment was applied to 248 the MODIS-derived data. "Good quality" pixels were selected, based on the quality as-249 surance (QA) flags. Next, an autoregressive model was applied to fill in the gaps (Akaike, 250 1969). The gap-filling procedure was applied to gaps smaller than 16 days, while gaps 251 of longer periods were excluded from the analysis. Finally, we implemented a temporal 252 filter to improve the f_{PAR} and LAI time series to reproduce precisely all pre-processing 253 steps of the standard PM-MOD algorithm (Mu et al., 2011). Filtering of f_{PAR} and LAI 254 allowed for the correction of underestimated values (abrupt and unrealistic decreases in 255 the time series) that mostly originate from cloud contamination effects which were not 256 correctly identified in the quality control fields. 257

232

2.3 Summary of remote sensing-based ET models

2.3.1 GLEAM

GLEAM is a semi-empirical/process-based model that estimates the total evapo-260 rative flux and its components. In this study, version 3 of the algorithm is used (Martens 261 et al., 2017). The main aspects of the model are described briefly, while for details we 262 refer to Miralles et al. (2011) and Martens et al. (2017). The model calculates potential 263 evaporation for four sub-grid land cover fractions: (1) open water, (2) low vegetation, 264 (3) tall vegetation, and (4) bare soil using the Priestley and Taylor (1972) equation. For 265 tall and low vegetation cover fractions, potential transpiration is constrained using an 266 empirical evaporative stress factor which is calculated as a function of soil moisture at 267 root-zone depth and microwave VOD as described in Martens et al. (2017). VOD (Veg-268 etation Optical Depth) accounts for the attenuation of microwaves through vegetation 269 and can be used as a proxy for vegetation phenology. Thus, VOD is a microwave pa-270 rameter closely linked to vegetation water content (Liu et al., 2013) and in GLEAM it 271 is used to represent phenological changes in vegetation. The soil moisture in the root-272 zone is calculated with a multi-layer water-balance model forced by precipitation and 273 satellite surface soil moisture retrievals. For bare soil, the evaporative stress factor is cal-274 culated as a function of surface soil moisture only, whereas for open water evaporation, 275 no stress factor is applied. For the tall vegetation cover fraction, rainfall interception loss 276 is estimated with Gash's analytical model (Gash, 1979; Miralles et al., 2010). The ET 277 is then calculated as the sum of low and tall vegetation transpiration, rainfall intercep-278 tion loss, bare soil evaporation, and open-water evaporation with each weighted by the 279 respective fraction. 280

2.3.2 PT-JPL

281

296

The global ET model proposed by Fisher et al. (2008) is based on the Priestley and 282 Taylor equation for potential ET (PET), which is partitioned into actual plant transpi-283 ration, soil evaporation, and interception evaporation, i.e. $E_{trans} + E_{soil} + E_{int}$. To re-284 duce potential ET to actual ET, the PT-JPL model applies ecophysiological constraints 285 based on land surface information such as vegetation properties and humidity/water va-286 por pressure deficit (VPD). Fisher et al. (2008) used NDVI and SAVI as a proxy for 287 plant physiological status. We used EVI because it provides a better indication of green 288 vegetation cover than NDVI, as acknowledged by Fisher et al. (2008). The model par-289 titions available energy flux using four plant-related constraints: LAI, green canopy frac-290 tion, plant temperature, and plant moisture. Similar to PM-MOD (see next subsection), 291 vegetation cover, canopy wetness, etc. determine how the available energy flux is par-292 titioned among the ET terms. A unique aspect related to the plant temperature con-293 straint is the determination of an optimal temperature, T_{opt} (Potter et al., 1993), which 294 corresponds to an optimal stomatal conductance. The latter co-determines E_{trans} . 295

2.3.3 PM-MOD

The MOD16 ET model (PM-MOD) is based on the Penman-Monteith equation to 297 produce a daily global ET product summing up daytime and nighttime ET (Mu et al., 298 2011). In this model, total ET is partitioned into E_{soil} , E_{int} , and E_{trans} . To compute 299 E_{soil} , PM-MOD uses potential soil evaporation and a soil moisture constraint function 300 based on VPD and air relative humidity (RH) (Fisher et al., 2008). The evaporation 301 of the water intercepted by the canopy, E_{int} , is calculated using the relevant equations 302 from a revised version of the Biome-BGC model (Thornton, 1998). The PM-MOD as-303 sumes that E_{int} occurs when the vegetation is covered with water, i.e. when the water 304 cover fraction $(f_{wet}) > 0$, which is constrained by RH (Mu et al., 2011). In the PM-305 MOD model f_{wet} is calculated as in the PT-JPL model: f_{wet} is set to 0 if RH < 70%306 and $f_{wet} = (RH/100)^4$ if 70 < RH < 100% (Running et al., 2019). The PM-MOD 307 model is designed to allow E_{trans} to occur during daytime and nighttime, by adding con-308 straints to stomatal conductance for VPD and minimum air temperature, and ignor-309 ing constraints relating to high air temperature (Running et al., 2019). The partition-310 ing of available energy flux into soil or interception evaporation is based on vegetation 311 cover (Fc), which is assumed to be equal to f_{PAR} from the MODIS product MOD15A2 312 (Mu et al., 2011). Although this method is based on the PM equation, PM-MOD does 313 neither require wind speed nor soil moisture data for the parameterization of aerodynamic 314 and surface resistance. Further details about PM-MOD can be found in Mu et al. (2011) 315 and Running et al. (2019). Note that some updates have been implemented in PM-MOD 316 since Mu et al. (2011), which can be found in Running et al. (2019). These were also con-317 sidered here in the implementation of PM-MOD. 318

319 2.3.4 PM-VI

This model relies upon the hypothesis that ET is mostly controlled by specific dom-320 inant processes, such as transpiration and photosynthesis, hence a good correlation be-321 tween such processes and ET is necessary for good model performance (Nagler et al., 322 2007). There are several formulations to estimate ET from VIs (Nagler et al., 2005, 2009). 323 In this study, we selected the algorithm proposed by Nagler et al. (2013), which estimates 324 ET using the reference crop evapotranspiration, ETo, from the FAO-56 Penman-Monteith 325 (PM) equation (Allen et al., 1998), and a crop coefficient, Kc_{VI} , derived from a vege-326 327 tation index. Kc_{VI} can be calculated in different ways (Nagler et al., 2005, 2013). Following Nouri et al. (2016) and P. T. S. Oliveira et al. (2015), Kc_{VI} was calculated as: 328

$$Kc_{VI} = a\left(1 - e^{-b \times EVI}\right) - c \tag{1}$$

where a, b and c are fitted coefficients. We used a parameter optimization tool based on a genetic algorithm to optimise the coefficients to estimate ET values close to the measured ones (P. T. S. Oliveira et al., 2015). The fitting procedure minimizes the objective function (OF) given by the sum of squared differences between tower-based ET (ET_{obs}) and ET estimates from the models (ET_{sim}) at time *i*:

$$OF = \sum_{i=1}^{n} \left[ET_{obs}(i) - ET_{sim} \right]^2$$
(2)

This model, herein referred to as PM-VI, has frequently been employed to estimate 334 ET at local and regional scales (P. T. S. Oliveira et al., 2015; Nouri et al., 2016; Jarchow 335 et al., 2017). Although obtaining ETo requires a considerable amount of meteorologi-336 cal variables, the PM-VI implementation is easier and has a lower computational cost 337 compared to other models. Unlike the three other models, PM-VI requires the calibra-338 tion of the fitting coefficients, which can be a major issue for regions where ET and VI 339 are poorly correlated or when correlations change over time (Chong et al., 1993). To cal-340 ibrate the fitting coefficients, we randomly selected 20% of the available data at each site 341 and used the remaining 80% to validate the model. 342

343

2.4 Quantifying model reliability

The model predictive skill was visually evaluated with scatter plots of measured 344 versus modelled ET, as well as through the coefficient of determination (R^2), root mean 345 square error (RMSE), percent bias (PBIAS), concordance correlation coefficient (ρ), 346 slope (m), and intercept (b) of the linear regression. The data used in the analysis were 347 filtered for rainy days (P > 0.5 mm). Our analysis proceeded from a general (no dis-348 tinction among sites) to a site-by-site and group level analysis, i.e. per biome, climate, 349 or land use. The number of flux towers assigned to each subgroup (i.e., the different biomes, 350 climate, and land use classes) varied, and so did the record length per subgroup. To ac-351 count for the different sizes, the following sampling procedure was performed, in which 352 we computed the variability of each performance metrics for each group analysis (i.e., 353 across its different subgroups): (i) A sample size N was defined as half of the record length 354 of the shortest subgroup, among all models; (ii) for each model, samples of length N were 355 taken from within each subgroup, and the performance metrics were computed; (iii) This 356 procedure was repeated 1000 times, yielding a mean and standard deviation (SD) of the 357 metrics at each subgroup, per model. The resulting SD are likely to be influenced by the 358 choice of N, and other rationale for its choice could have been made. In this way the con-359 fidence bands reported here are to be seen as measures of relative variability, i.e., the vari-360 ability between the models, and not as absolute uncertainty bounds for each of them. 361 To establish a relationship between model predictive skill and water availability at in-362 dividual tower sites, we obtained the aridity index (AI = P/ETo) from the global dataset 363 provided by Trabucco and Zomer (2019). For many tower sites, the available meteoro-364 logical data (even from nearby meteorological stations) were not sufficient to provide a 365 reliable AI; hence the choice for a global dataset. 366

367 3 Results

368

3.1 ET partitioning

Partitioning of ET among the three components (E_{trans} , E_{int} and E_{soil}) exhibited more variation for the PT-JPL and PM-MOD models. On average, E_{trans} accounted for 60% (PT-JPL) and 56% (PM-MOD) of ET but, across sites, it presented a smaller range (30% to 85%) for PT-JPL than for PM-MOD (20 to 90%) (Figure 2, Table 1). GLEAM E_{trans} accounted for 82% of ET on average, varying between 60% and 95% across sites. Average interception across sites reached 9% (GLEAM), 13% (PT-JPL), and 24% (PM- MOD) of total *ET*. E_{int} fractions range were similar for GLEAM and PT-JPL ($SD \approx$ 9%), whereas PM-MOD E_{int} varied more among sites (SD = 18%). E_{int} was often correlated with *LAI*, especially for the GLEAM estimates ($R^2 = 0.57$, Figure S2 in SM). PT-JPL E_{soil} estimates exceeded the other models, particularly for sites with low *LAI* walkers (a = ESEC, *CCT*, and *USD*).

values (e.g., ESEC, CST, and USR).

Figure 2. Evaporation fractions estimated by the models at each site (stacked bars) and average partitioning of land evaporation per model (pie diagram). Black dots: LAI scaled between 0 and 1 based on the minimum and maximum values of LAI (from MODIS MDC15A2 product). Red \times : the concordance correlation coefficient between observed and simulated daily ET.

380 3.2 Overall model skills

Since each model requires a different input dataset (Table S3, SM), the data available to run and validate each model varied. GLEAM and PT-JPL provided a significantly greater number of daily outputs: 7301 (GLEAM), 7277 (PT-JPL), 5905 (PM-MOD), and 6638 (PM-VI). The complete data set was used to produce scatter plots of *ET* records and model simulations for each location (See Figures S4-S7 in SM). To allow a fair analysis, the results shown in the main text were obtained using data from days that were common across models, resulting in 4718 data points.

To illustrate the relative contribution of each site to the scatter plots in Figure 3, 388 we display the regression lines (light grey lines) between model and tower-based ET for 389 each tower site, and the mean metrics across individual sites. In general, ET was rea-390 sonably predicted by all models, as suggested by the relatively low spread of most points 391 in the scatter plots, many regression lines close to the 1:1 line, mean determination co-392 efficient, R^2 , mean concordance correlation coefficient, $\overline{\rho}$, mostly above 0.65, and mean 393 root mean square error (\overline{RMSE}) below $1 \,\mathrm{mm}\,\mathrm{d}^{-1}$ (Figure 3). Nevertheless there is some 394 spread for a few sites, e.g., in the PT-JPL scatter plot that displays a few sites with large 395 bias despite strong overall correlation and ρ . 396

The models slightly overestimate ET as suggested by higher density of points be-397 low the 1:1 line, except for GLEAM, which slightly underestimates. Correlations were 398 similar between GLEAM and PT-JPL, with an average value of ~ 0.65 and the highest 399 values at individual sites reaching close to 0.9, as indicated by the standard deviations 400 (0.19 and 0.18, respectively). From Figures 3 and 4, it becomes evident that, despite the 401 relatively lower spread of points for PM-VI, compared to the other models, this model 402 (PM-VI) presented a less consistent performance across towers, as suggested by the con-403 trasting slopes presented by the regression lines in that plot (e.g. reversed trend line at 404 K77); hence the lower average determination coefficient (R^2) and $\overline{\rho}$. Such contrasting 405 aspect of the PM-VI model is also noted by the fact that a wide range of R^2 was found 406 despite the similarity between mean simulated and observed ET (Figure 4)., 407

Figure 3. Scatter plots of observed vs. simulated daily evapotranspiration at all flux tower sites, for each model. The light grey lines show the regression slope of individual sites. The coefficient of determination (R^2) , root mean square error (RMSE) and concordance correlation coefficient (ρ) were averaged across towers and are displayed on the plots (N = 4,718).

Figure 4. Comparison of mean observed and simulated ET. Circle colors vary according to individual model R^2 .

Figure 5. Model performance per biome, land use and climate. The error bars represent the standard deviation of the metrics within each class. Biome types: Tropical & Subtropical Moist Broadleaf Forests (TSMBF); Tropical & Subtropical Dry Broadleaf Forests (TSDBF); Temperate Grasslands, Savannas & Shrublands (TGSS); Temperate Broadleaf & Mixed Forests (TBMF); Tropical & Subtropical Grasslands, Savannas & Shrublands (TSGSS); Flooded Grasslands & Savannas (FGS); Land use types: Cropland (CROP); Woodland Savanna (WS); Deciduous Needleleaf Forest (DNF); Evergreen Broadleaf Forest (EBF); Grasslands (GRA); Mixed Forest (MF); Permanent Wetland (PW); Deciduous Broadleaf Forest (DBF). Climate Zones: Tropical monsoon (Am); Tropical savanna (Aw); Hot semi-arid (BSh); Cold semi-arid (BSk); Temperate oceanic (Cfb); Dry-winter subtropical highland (Cwb); Polar Tundra (Td).

3.3 Model skills per biome, land use, and climate

Figure 5 presents ρ , RMSE, PBIAS, and R^2 for each model across six biomes, 409 eight land use types, and seven climate classes in South America. Error bars are shown 410 for all metrics, and they represent the standard deviation resulting from the resampling 411 procedure outlined in 2.4. Note that the analysis about the FGS and TBMF biomes are 412 based on one and three towers, respectively. For most biomes, RMSE and R^2 did not 413 significantly diverge. In general, TSGSS showed the best overall metrics for all models, 414 while PM-VI in FGS (NPW site) presented the poorest ($\rho < 0.5, RMSE > 1.5 \,\mathrm{mm}\,\mathrm{d}^{-1}$ 415 and $R^2 < 0.25$). Model performance across towers within each biome did not vary much, 416 as suggested by the relatively low range of the error bars for all metrics. 417

The central panels in Figure 5 provide evidence for the high variability of model 418 predictive skills across different land uses (LU), which suggest that: (i) no model out-419 performs the others for all LU types, (ii) each model has intrinsic and in some cases ex-420 clusive characteristic that makes it more suitable for certain LU. Only for croplands (CROP) 421 we found similar metrics among models ($\rho \approx 0.8, 0.8 < RMSE < 1.2 \,\mathrm{mm}\,\mathrm{d}^{-1}, -20\% < 0.8$ 422 $PBIAS < 10\%, 0.6 < R^2 < 0.8$). Conversely, for most LU, the metrics variation is 423 remarkable (e.g., DBF: $0.4 < \rho < 0.9, -50\% < PBIAS < 10\%, 0.25 < R^2 < 0.80$). 424 On average, each model has the best skills for two LU; e.g., ET prediction for GRA and 425 DBF was best with PT-JPL ($\rho \approx 0.9, RMSE \approx 0.5 \,\mathrm{mm}\,\mathrm{d}^{-1}, PBIAS \approx 0\%, R^2 >$ 426 0.75) whereas PM-VI presented similar skills for estimation of ET for CROP and PW. 427 Likewise, model skill is related to the climate type. The analysis of ρ and R^2 over semi-428 arid regions (BSk and BSh) indicates a relatively poor skill of all models (except PM-429 MOD for BSh climate). This is in contrast to the overall good performance over more 430 humid environments (e.g., Aw and Cwb). The greatest divergence among model perfor-431 mances was found for the Polar Tundra (Td) climate zone, for which PM-VI presented 432 the highest ρ and R^2 (both > 0.75), lowest RMSE (~ 0.5 mm d⁻¹) and PBIAS (< 433 10%). 434

3.4 Individual sites

408

435

In this section, we explore the model performance at individual towers. Model skills for all individual sites are depicted in Figure 6. Sites with N < 30 (CAX and MCR) are not discussed here but are considered in the scatter plots shown in the SM (Figures S4-S7). To facilitate the comparison of our results with previous analyses using the same models, only three statistics are shown in Figure 6: RMSE, PBIAS, and R^2 . Other metrics are displayed in the scatter plots in Figures S4-S7 in the SM. In Figure 6, the metrics for the various towers are displayed in order of increasing aridity (varying from ~ 3 to 0, left to right), as suggested by the AI as described in Section 2.4). In general, there is a good agreement between the PM-based models in terms of *RMSE* and *PBIAS*.

In terms of individual metrics, RMSE values varied between ~ 0.5 and ~ 1.5 mm d⁻¹ 445 for all models, with $RMSE < 1 \text{ mm d}^{-1}$ for most sites. The boxplots show that RMSE446 variation is similar among models, except for PT-JPL which presents the lowest RMSE447 (e.g., K67). Figure 6 shows that *PBIAS* for PM-VI varies around zero across sites, which 448 449 is expected given the model requires calibration with local data. However, based on R^2 , it is apparent that this model's skill is quite limited for $AI > \sim 1.2$ and $AI < \sim 0.5$. In 450 general, the PT-based models showed larger biases, with PT-JPL and GLEAM consis-451 tently overestimating and underestimating ET, respectively. In terms of R^2 , the PT-models 452 ranked better than the PM-models for more than $\sim 50\%$ of the towers. 453

Figure 6. Comparison of statistics of the models in estimating evapotranspiration (ET) for the various flux towers used. (a) Sample size (N) used to compute the statistics; (b) RMSE= Root Mean Square Error; (c) Percent Bias (PBIAS); (d) R^2 = coefficient of determination. A summary of each model's statistics is depicted in the boxplots: (e) RMSE; (f) PBIAS; (g) R^2 . Flux towers are arranged according to the aridity index (with aridity increasing from left to right). Sites with N < 30 (CAX and MCR) are not shown here

$_{454}$ 4 Discussion

455

4.1 General implications

We conducted the first multi-remote sensing ET model analysis in South Amer-456 ica (SA) using a common set of forcing and validation data located on flux tower sites 457 across a diverse range of land covers, climates, and biomes. Forcing data include both 458 in situ (e.g., temperature and net radiation) and remote sensing data, mainly related 459 to vegetation (e.g., LAI and EVI). To evaluate the models, energy balance-derived ET460 (ET_{EB}) was used as observation, instead of eddy covariance $ET (ET_{EC})$. Given the ben-461 efits and drawbacks of using either ET_{EB} or ET_{EC} , we compared both measures to ver-462 ify whether such choices would lead to different results. As shown in the SM, for the great 463 majority of tower sites, ET_{EC} and ET_{EB} are similar (Figure S10) and model statistics 464 $(R^2, RMSE \text{ and } \rho)$ remained the same regardless of the ET approach or indicate a bet-465 ter performance when ET_{EB} was used (Figures S11-S13 in the SM). Many of the tower 466 sites considered here are not yet available in flux network databases, including sites with 467 land cover (deciduous needle-leaf forests, DNF), a biome (FGS), and two climate types 468 (polar tundra, hot semi-arid) that have not been previously assessed in other regional 469 studies on the performance of satellite-based ET models. Moreover, some classes included 470 here were considered for validation of individual models only (e.g., semi-arid and trop-471 ical climate types, and TSDBF biome). 472

The fulfillment of such gaps (i.e. model evaluation across uncharted regions) is an 473 important step because it allows a multitude of applications and studies relying on large 474 scale ET mapping, such as: drought monitoring (Anderson et al., 2011, 2016), agricul-475 tural water management (Anderson et al., 2012), diagnosis of climate change (Mao et 476 al., 2015). The current ability to map ET remotely at various spatial and temporal scales, 477 could only be evaluated thanks to the vast number of eddy covariance towers available 478 in continental and global flux networks. As shown in this study, a thorough assessment 479 of RBSET models based solely on data from such networks would be challenging or in-480 sufficient for some regions or continents; hence the relevance of this study. Our analy-481

sis provides essential information to identify model strengths and limitations across SA, 482 allowing the users to identify which model is more suitable for them. Knowing under what 483 circumstances, e.g., land use or climate, each model is more reliable is necessary to ad-484 dress remaining research and applied science gaps relative to ET at local, regional and global scales (Fisher et al., 2017). Despite the value of tower-based ET across SA, many 486 of those questions persist due to our limited observational capabilities. According to Fisher 487 et al. (2017), the way to begin answering those questions is producing high quality ET 488 estimates, which includes acquiring accurate ET information at high temporal and spa-489 tial resolution with large spatial coverage for a sufficient long period. 490

491

4.2 Model performance, sources of errors and ET partitioning

Generally, model predictive skill over SA resembles what has been reported for other 492 continents, including satisfactory values of coefficient of determination $(R^2 > 0.6)$ of the 493 models (except PM-VI) for most validation sites, and consistently better results for the 494 GLEAM and PT-JPL models, with RMSE ranging from ~ 0.5 to 1.5 mm d⁻¹ (McCabe 495 et al., 2016). Also, in accordance with previous analysis, GLEAM and PT-JPL presented 496 somewhat higher RMSE than PM-MOD but no clear evidence indicates decreasing per-497 formance with increasing aridity, as reported by McCabe et al. (2016); Michel et al. (2016). 498 Nonetheless, the general analysis (Section 3.2) indicates that all models can be used re-499 liably over most of the environmental conditions in SA covered in our study. The anal-500 ysis across towers and groups (i.e., biome, land use type and climate, Section 3.3, Fig-501 ure 5) identified considerable differences in terms of model skill. 502

Our results agree with previous studies from (Ershadi et al., 2014; McCabe et al., 503 2016; Michel et al., 2016; Miralles et al., 2016) who applied PM-MOD, GLEAM (except 504 Ershadi et al. (2014)) and PT-JPL to sites located in Africa, Asia, Australia, Europe and 505 Middle East and reported that PM-MOD showed, for most sites, lower correlations with 506 measured ET compared to GLEAM and PT-JPL. Unlike previous analysis, our study 507 agrees with Michel et al. (2016) in the sense that model skill seems to be unrelated to 508 land cover. Michel et al. (2016) also reported a wide variation of R^2 (0.2–0.8) and RMSE509 $(0.8-2 \text{ mm d}^{-1})$, for different sites under mixed forests. Conversely, contrasting results 510 between our results and previous studies were found for woodland savanna. While we 511 found $0.5 < R^2 < 0.8$ and $0.7 < RMSE < 1.5 \text{ mm d}^{-1}$, Michel et al. (2016) reported 512 $R^2 < 0.2$ and $1 < RMSE < 3 \,\mathrm{mm} \,\mathrm{d}^{-1}$. 513

Overall, our group-wise analysis based on climate agrees with previous studies. For 514 example, the poor model skill found here for the cold semi-arid (Bsk) climate $(0.1 < R^2 <$ 515 (0.5) resembles that found by Michel et al. (2016) and McCabe et al. (2016) for several 516 sites in the United States. While aridity could have played a role here, it could also be 517 caused by the fact that semi-arid sites are covered with sparse canopies. Such canopies 518 present challenges when it comes to the description of aerodynamic transfer for exam-519 ple and radiation partitioning (see e.g Verhoef and Allen (2000)). Our findings also show 520 a poor to moderate model skill for ET predictions for sites located in the Cfb climate 521 zone, with PM-MOD having the worst performance. Conversely, PM-MOD presented 522 the best predictive skill for the BSh climate, according to most metrics. 523

Besides the three RSBET models commonly assessed (GLEAM, PT-JPL, and PM-524 MOD), our analysis included the PM-VI model, which has been validated mostly for crop-525 land or riparian ecosystems (Nagler et al., 2005, 2009, 2013; Jarchow et al., 2017). Here, 526 we tested PM-VI for a much wider variety of biomes, climates and land uses, and found 527 a poor predictive skill for several sites with AI > 1.2 (e.g K67, K77, K83) or AI <528 0.5 (e.g., CAA and SLU), even though the model accounts for a site-specific calibration. 529 Considering the good results obtained for $\sim 50\%$ of the towers and the fact that, com-530 pared to the other models, PM-VI has a much simpler implementation, this model does 531 have potential as long as sufficient data are available for calibration or, at least, valida-532

tion. However, the need for local calibration is a hurdle for its implementation for most
regions that are unsampled; therefore future studies are necessary to investigate which
factors are most relevant in the determination of the model fitting coefficients, and to
provide distributed reference values for its coefficients (e.g., based on land use dynamics).

We were able to identify a number of probable causes for poor model performance 538 at individual sites, including (i) patch-scale heterogeneities; (ii) "mixed pixels", i.e. mixed 539 response of different vegetation types within a pixel; (iii) time-lag between ET_{obs} and 540 EVI; (iv) model sensitivity to individual inputs; (v) low correlation between ET and 541 vegetation indices (see Section 3.0 in the SM for more details). Although we did not ver-542 ify this in our study, we did not dismiss the possibility that known uncertainties in the 543 estimation of site-specific vegetation characteristics (e.g., f_{PAR} and leaf stomatal con-544 ductance in the PM-MOD; Ershadi et al. (2014)) are further causes of lower model per-545 formance. 546

In our study, we used soil heat flux (G) which is generally measured below ground 547 (usually at 5–20 cm deep) using soil heat flux plates. It could be argued that not cor-548 recting G for the heat storage between the plate and the soil surface could lead to sub-549 optimal estimates of ET when LE is calculated as the residual of the energy balance, 550 especially for towers where the soil is bare or covered by sparse vegetation, where G can 551 be relatively large. This, in turn, could lead to the conclusion that the models are per-552 forming worse than is actually the case. Although desirable, correcting G for heat stor-553 age is rarely possible due to data unavailability (few sites only measure soil moisture and 554 temperature, which are required to estimate soil heat capacity, and heat storage using 555 the calorimetric method). Moreover, at daily scales and for most sites, G is either neg-556 ligible in SA (summer or winter, when the amount of heat stored during the day roughly 557 equals that lost during the night) or represents a minor portion only (spring and autumn) 558 of the energy balance. As detailed and discussed in Section S3.0 and Figure S7 in SM, 559 it is highly unlikely that neglecting such corrections will have affected the results. 560

There are, however, some issues worth mentioning here. Cause (v), for instance, 561 is a major issue for PM-VI, as expected because the model is highly dependent on VI 562 dynamics (see Section 2.4) (Nagler et al., 2005). Regarding cause (iv), the superior per-563 formance of the PT models over PM-MOD at most sites is probably linked to uncertain-564 ties resulting from the estimation of aerodynamic resistance (Ershadi et al., 2014). In PM-MOD, the aerodynamic and surface resistances of each ET component (soil, inter-566 ception, and transpiration) are parametrized based on biome-specific values of leaf-scale 567 boundary layer conductance, for example (Mu et al., 2011). Compared to the previous 568 version of PM-MOD (Mu et al., 2007), this new approach resulted in a perceptible im-569 provement only for cropland and deciduous broadleaf forest flux tower sites, whereas for 570 other land uses no meaningful change was reported (Ershadi et al., 2015). Conversely, 571 PT models are highly dependent on Rn (causes iv and v); hence they often fail in dry 572 environments (see metrics for $AI < \sim 0.6$ in Figure 6) where ET seasonality is dictated 573 by P more than radiation, or in regions with low Rn (e.g., TF2). Poor model responses 574 at K77 (cropland, Figure S9 in SM) were attributed to causes (i) and (ii), as remnants 575 of forest and shrubs were identified within the tower footprint and within MODIS pixel. 576 VI products with higher resolution than MODIS exist and have been used to estimate 577 ET (Aragon et al., 2018; Fisher et al., 2020); thus offering a possible solution for causes 578 (i) and (ii). Time lag between ET and EVI (cause iii) was identified at EUC, where EVI 579 followed the decline of ET after $\sim 1-2$ months . 580

Regardless of all those potential causes for poor model response, it is also important to consider to role of the core formulation upon which those RBSET models are based, i.e. Penman-Monteith (PM) and Priestley and Taylor (PT) equations. A major problem of the PM equation refers to the linearization of the Clausius-Claperyron relation, which has been addressed in a new version of that equation(McColl, 2020). The PT equation, in turn, implicitly assumes Rn and surface temperature (T_s) to be independent of evaporation. In reality, as shown by Yang and Roderick (2019), Rn not only decreases with increasing T_s (due to an increase of outgoing longwave radiation) but also a greater fraction of Rn becomes available for evaporation. Some of the deviations from the observations found in our analysis may happen due to such inconsistencies or simplifications. Here, we provide evidence to consider revisiting not just parameter values but the governing equations themselves and, ultimately, evaluate the benefits of such potential improvements in RBSET models.

Remote sensing based ET partitioning is expected to present some divergences from 594 ground based measurements. This is the case especially for E_{soil} , because of the diffi-595 culty in obtaining remote sensing information on soil characteristics that drive E_{soil} , such 596 as soil moisture and temperature (Talsma, Good, Jimenez, et al., 2018; Talsma, Good, 597 Miralles, et al., 2018), in particular at high vegetation cover fractions. Globally, tran-598 spiration has been reported to account for 57-90% of global ET, based on in situ data 599 and model outputs (Jasechko et al., 2013; Wei et al., 2017; Paschalis et al., 2018). Al-600 though these are global estimates, we expected E_{trans} to be the largest ET component 601 also in SA due to its prevailing tropical climate and corresponding vegetation types. Our 602 results show that this was indeed the case for GLEAM with an E_{trans}/ET ratio of ~80%, 603 and for PT-JPL and PM-MOD with values of 57 and 60%, respectively. Nonetheless, based 604 on our findings, model predictive skill in estimating total ET is not necessarily associ-605 ated with its ability to partition ET accurately. 606

Concomitantly, inconsistencies in ET partitioning do not necessarily translate into 607 inaccurate model estimates of total ET: this depends on the modelling approach. On 608 the one hand, if total ET results from the sum of ET components independently, then 609 an under- or overestimation of ET components can reduce the overall model skill, or rea-610 sonable ET estimates can be achieved as the consequence of an occasional compensa-611 tion of errors in E_{trans} , E_{soil} and E_{int} . On the other hand, if the ET partitioning is de-612 rived from the estimate of a proxy value for total ET, such as available energy flux (as 613 in PM-MOD and PT-JPL), the ET partitioning is unlikely to influence the total ET es-614 timates. Moreover, ET partitioning may be sensitive to certain model inputs. For ex-615 ample, contrasting ET fractions were estimated by PM-MOD for similar rain forest sites, 616 i.e. K67 and K83 (Figure 2). The reason PM-MOD is returning that difference is be-617 cause RH was estimated from actual (e_a) and saturation vapor pressure (e_s) data, as 618 RH data is not available in K83 dataset. As a result, the difference between e_a -derived 619 daytime and nighttime RH for K83 is greater than that for K67. In terms of daily av-620 erages, e_a -derived RH and measured RH are quite similar, which explains why the frac-621 tions for GLEAM and PT-JPL, at those two towers, are similar. Still, good estimates 622 of ET components are important to differentiate the roles of vegetation and soil, i.e., how 623 they contribute to vertical soil water fluxes and changes in profile soil water content. Re-624 liable knowledge of the distribution between E_{soil} and E_{trans} is also important when this 625 information is used in hydrological models to calculate other water balance components, 626 such as runoff. 627

Ground-based ET partitioning data are generally not widely available. This also 628 goes for most land cover types included in this study. We compared the models' outputs 629 with field experiment studies that measured one or more ET components either at the 630 same sites as those used here or within the same region (Table 1). ET partitioning val-631 ues derived from GLEAM seem to be more consistent with ground-based information 632 available for tropical rain forests, croplands and grasslands than for wetlands, and mixed 633 and deciduous needle-leaf forests (Table 1). This also applies to PT-JPL with its ET par-634 titioning agreeing reasonably well with observations made for both tropical rain- and dry 635 forests. Note that PT-JPL (as well as PM-MOD) constrain E_{trans} based on f_{wet} . Hence, 636 compared to GLEAM, transpiration will be lower under high RH in the model but ET637 can be high due to water availability in the soil and intercepted rainfall. Nonetheless, 638

the overall predictive skill of PT-JPL was satisfactory at such sites (Figure 6 and Fig-639 ure S4 in SM). Regarding PM-MOD, the main inconsistency is the E_{inter} for tropical 640 forests (Table 1). Despite the wide variability in E_{trans}/ET among models, their over-641 all predictive skill was satisfactory, that is, not associated with their capability to cor-642 rectly estimate each ET component individually (see SM for further discussion). No model 643 was able to consistently capture the ET partitioning across all sites correctly, which is 644 expected given the uncertainty of each ET component and the climate and land-cover 645 variability in SA. However, the joint estimates of all models covered totally or partially 646 all field-derived evidence on ET partitioning. This suggests that continental ET esti-647 mates for understudied regions, such as the SA, would benefit from merging ET outputs 648 from models that are based on different methods (Paca et al., 2019). 649

Despite our efforts to gather as much tower data as possible, with the goal of hav-650 ing a common data set for all models, we faced several limitations including: differences 651 in lengths of observational time series across towers (up to 3 years), as well as lack in 652 overlap of these time series; uneven distribution of towers across groups (e.g., biomes); 653 and, finally, South American geographical features that were not considered in this study 654 (e.g., MGS biome or desert climate type, BWk). Thus, it was not possible to assess, for 655 all towers, model responses during all seasons. Nonetheless, the fact that our dataset en-656 compasses a wide variety of climates enabled us to evaluate, to a reasonable extent, model 657 responses for contrasting seasons and fill in the gaps flagged by the literature, such as 658 the absence, in a similar analysis, of towers in the tropical climate zone pointed out by 659 McCabe et al. (2016). 660

⁶⁶¹ 5 Conclusion

Our results show that, in general, ET can be reasonably well predicted by all four 662 models, despite an overall tendency of overestimation by PT-JPL and PM-MOD, and 663 underestimation by GLEAM. Contrasting with results from other continents, we found 664 no clear evidence linking model predictive skill with aridity. Our analysis emphasizes the 665 need of improving model ET partitioning, although the link between flawed ET parti-666 tioning and poor model skill is not evident based on our results. Having reliable ET par-667 titioning coefficients as part of the FLUXNET-type datasets would be valuable in this 668 respect, but unfortunately such data are difficult to obtain, as they require labour-intensive 669 and expensive methods (such as sapflow gauges and lysimeters), that also present prob-670 lems with regards to upscaling from plot to field-scale. 671

⁶⁷² Correlations are consistently higher for GLEAM and PT-JPL, with $R^2 > 0.5$ for ⁶⁷³ most sites, whereas PM-MOD and PM-VI presented better performances in terms of PBIAS ⁶⁷⁴ (-10 < PBIAS < 10% for most sites). As for PM-VI, the low PBIAS is expected, ⁶⁷⁵ given the model requires calibration with local data.

The model skill for the various models seems to be unrelated to land cover type as we found a wide variability of metric values within the same class and across models. Conversely, a relatively lower performance was observed for most models in semiarid regions, compared to an overall good performance for more humid environments. Except for the FGS biome, we found that skill across models was mostly similar within the same biome.

Despite the relatively high number of towers (compared to previous global analyses that used a similar amount of sites), gathering a balanced amount of data and uniform distribution of towers across different biomes and climate zones across the whole continent was challenging. Thus, there is a need to expand the flux tower network in South America as well as the formation of bilateral collaboration for future contributions. Previous studies (Michel et al., 2016; McCabe et al., 2016) have expressed the need to extend the evaluation of RSBET models to uncharted biomes and climate conditions. Our analysis fills this gap by assessing the reliability of four RSBET models over South Amer-

 $_{690}$ ica. We provide benchmarking metrics that can serve the improvement of ET models

for improved capturing of ET over this continent.
