**Abstract.** Multiband downwelling thermal measurements of zenith sky radiance, along with cloud boundary heights, were used in a retrieval algorithm to estimate cloud optical depth and effective particle diameter of thin ice clouds in the Canadian High Arctic. Ground-based thermal infrared (IR) radiances for 150 semitransparent ice clouds cases were acquired at the Polar Environment Atmospheric Research Laboratory (PEARL) in Eureka, Nunavut, Canada (80° N, 86° W). We analyzed and quantified the sensitivity of downwelling thermal radiance to several cloud parameters including optical depth, effective particle diameter and shape, water vapor content, cloud geometric thickness and cloud base altitude. A lookup table retrieval method was used to successfully extract, through an optimal estimation method, cloud optical depth up to a maximum value of 2.6 and to separate thin ice clouds into two classes: (1) TIC1 clouds characterized by small crystals (effective particle diameter  $\leq 30\ \mu\text{m}$ ), and (2) TIC2 clouds characterized by large ice crystals (effective particle diameter  $> 30\ \mu\text{m}$ ). The retrieval technique was validated using data from the Arctic High Spectral Resolution Lidar (AHSRL) and Millimeter Wave Cloud Radar (MMCR). Inversions were performed over three polar winters and results showed a significant correlation ( $R^2 = 0.95$ ) for cloud optical depth retrievals and an overall accuracy of 83 % for the classification of TIC1 and TIC2 clouds. A partial validation relative to an algorithm based on high spectral resolution downwelling IR radiance measurements between 8 and 21  $\mu\text{m}$  was also performed. It confirms the robustness of the optical depth retrieval and the fact that the broadband

thermal radiometer retrieval was sensitive to small particle (TIC1) sizes.

## 1 Introduction

Predictions of future climate change and its regional and global impacts require that a better understanding of the radiative transfer interactions between clouds, water vapor and precipitation are incorporated into appropriate models. Recent CMIP5 model intercomparisons (the Coupled Model Intercomparison Project as described in Jiang et al., 2012) indicate large variability in ice cloud parameters (for example ice water content) amongst high-latitude models. Shortcomings in ice cloud parameterization (Baran, 2012) impact their representation of radiative effects as well as water cycles and lead to uncertainties in quantifying cloud feedbacks in the context of climate change (Waliser et al., 2009). High-altitude thin ice clouds consisting of pure ice crystals, which cover between 20 to 40 % of the Earth (Wylie and Menzel, 1999), can, for example, have opposing effects on the radiative properties of the Earth. A surface-cooling effect ensues when scattering by clouds reduces the solar radiation reaching the Earth's surface (i.e., albedo effect). By contrast, a reduction in the amount of IR energy escaping the Earth–atmosphere system occurs when the upwelling IR radiation emitted by the Earth's surface and lower atmosphere is absorbed by clouds and radiated back downward (i.e., greenhouse effect; Stephens and Webster, 1981). The macrophysical and microphysical properties of thin ice clouds deter-

mine which process dominates and hence determine the net forcing of thin ice clouds on the climate system (Stephens, 2005). The optical properties of thin ice clouds can be represented by extensive parameters such as the optical depth and ice water content as well as intensive parameters such as ice crystal size and shape. In an Arctic environment, the radiative effects of ice clouds are unique because their radiative forcing influence on the energy balance depends on seasonal polar day to polar night variation as well as large-scale processes like the Arctic Oscillation (Wang and Key, 2003). The advent of active sensors on board satellites (for example CALIPSO/CloudSat) has enabled the application of considerably more resources for polar region ice cloud studies. This permits the evaluation of climate models (Jiang et al., 2012) and satellite cloud climatologies (Sassen et al., 2008). Long-term ground-based observations, which are also essential for the validation of models and satellite climatology, are, however, limited in their Arctic coverage (Heymsfield et al., 2017).

Thermal IR radiometry is a well-known technique for investigating the presence and the emissivity of clouds (Allen, 1971). Numerous researchers have exploited the thermal IR behavior of the absorption and scattering efficiencies of cloud particles as a means of retrieving CODs and particle effective sizes (e.g., Inoue, 1985). As cloud altitudes (temperatures) can lead to large uncertainties in this latter technique, Platt (1973) proposed using lidar backscatter profiles along with IR radiometry to estimate cloud altitudes and accordingly improve the retrieval accuracy of cloud emissivity. This active/passive technique (called LIRAD for lidar/radiometer method by Platt) has evolved over the years with improvements such as the availability of high-resolution spectrometers (Smith et al., 1993; Lubin, 1994). The LIRAD technique is based on spectral radiance/brightness temperature comparisons between measurements and radiative transfer calculations. It performs better in the presence of high thermal contrast and is thus well suited for cloud retrievals (Lubin, 1994). In more recent applications, cloud optical depth, effective radius and ice fraction were retrieved from AERI (Atmospheric Emitted Radiance Interferometer; Knuteson et al., 2004a, b) spectral downwelling radiance observations in Antarctic, during the surface heat budget of the Arctic Ocean (SHEBA) campaign and the ARM (Atmospheric Radiation Measurement) Alaska North Slope site (Turner et al., 2003; Shupe et al., 2015; Mahesh et al., 2001, respectively). The Turner (2005) method was also employed at Eureka (Nunavut, Canada) to retrieve cloud optical depth and cloud microphysical parameters from AERI spectra acquired between 2006 and 2009 (Cox et al., 2014). A proposed satellite-based instrument, with the goal of characterizing thin ice clouds in the Arctic using far and thermal infrared channels (Blanchet et al., 2011), was recently tested during an airborne campaign in the High Arctic (Libois et al., 2016).

In this paper, we examine how multiband thermal measurements of zenith sky radiance can be used to retrieve what are, as indicated in the early remote sensing literature (see, Nakajima and King, 1990, for example.), the most critical extensive and intensive parameters influencing the radiative effects of ice clouds: cloud optical depth (COD) and effective particle diameter ( $D_{\text{eff}}$ ). We propose an application of this LIRAD technique with a relatively simple and inexpensive instrument (less than 10 % of the cost of an AERI) which is well suited to the Arctic environment (Royer et al., 2014). Inasmuch as ice particle size is difficult to retrieve from IR radiometry, the  $D_{\text{eff}}$  component of our retrievals will be focused on a simple discrimination of large and small crystal sizes. This approach was motivated by previously published research that indicated such a discrimination would play a key role in characterizing an important aerosol–cloud interaction process in polar winter, namely precipitative cooling (see, for example, Blanchet and Girard, 1994; Grenier et al., 2009). An important aspect in this paper is that our COD and  $D_{\text{eff}}$  retrievals will be validated using independent lidar and radar retrievals.

Section 2 highlights the importance of studying ice clouds while Sect. 3 is devoted to the description of the study site and instrumentation. Section 4 examines the sensitivity of thermal IR radiometry to key ice cloud parameters. In Sect. 5 we describe and verify the proposed methodology for retrieving COD and  $D_{\text{eff}}$  using thermal IR radiometry measurements. The results are presented and discussed in Sect. 6 for the 150 thin ice clouds cases we observed in the Arctic.

## 2 Classification and parameterization of thin ice clouds

Water vapor and clouds are a significant climate modeling challenge since they represent major radiative forcing influences, while being the least understood components of the climate system (Waliser et al., 2009; Jiang et al., 2012). Much of the recent research has been focused on aerosol–cloud interactive processes involving aerosols acting as ice and water cloud nuclei as well as their subsequent effect on cloud microphysics, precipitation and radiation (see, for example, Feingold and McComiskey, 2016 on recent ARM campaigns, Winker et al., 2010 and Illingworth et al., 2015 respectively, on the cloud remote sensing mandate of the A-Train and EarthCARE satellite missions and Jouan et al., 2014 as part of the NETCARE project). In particular, understanding aerosols and their radiative effects, especially their indirect impacts as cloud condensation nuclei, is of critical importance for climate change models. The indirect effect of aerosols represents a cooling influence (amplitude is subject to large uncertainties) on the global radiative budget (Intergovernmental Panel on Climate Change, IPCC, 2013). The estimated uncertainty of the indirect forcing component (between  $-0.1$  and  $-1.3 \text{ W m}^{-2}$ ) is associated with variations in cloud properties and cloud lifetime. In the Arctic, the nature

of thin ice clouds can effectively induce an indirect cooling influence given the proper conditions. In terms of the purpose and motivation for this paper, we note that the presence of sulfuric-acid-bearing aerosols (viz., Arctic haze) can significantly increase the size of ice particles (relative to the size of ice particles formed from more pristine, low-acid aerosols or supercooled droplets). This process can cause enhanced precipitation and important cooling effects during the polar winter and could possibly lead to a dehydration greenhouse feedback (DGF) effect, as proposed by Blanchet and Girard (1994).

The small and large ice particles described above are often abbreviated as TIC1 and TIC2 (thin ice cloud, types 1 and 2). Thin ice cloud classification was carried out by Grenier et al. (2009) using the active techniques of lidar and radar: CALIPSO and CloudSat data were employed to discriminate between TIC1 and TIC2 ice clouds using the CloudSat small-particle sensitivity minimum of approximately 30–40  $\mu\text{m}$ . In this study, we seek to demonstrate that TIC1 and TIC2 discrimination can be determined using zenith-looking IR radiance measurements acquired at the Eureka observatory in the Canadian High Arctic. Figure 1 illustrates lidar and radar backscatter profiles acquired at Eureka for distinct TIC1 and TIC2 cases.

The left-hand lidar profile of Fig. 1 shows a TIC that is largely transparent to cloud radar while the right-hand lidar profile shows a thin ice cloud that is readily detected by the radar. The disparity in radar detectivity enables one to conclude that the former case corresponds to a small-particle TIC1 event while the latter case corresponds to a large-particle TIC2 event.

The presence or absence of thin ice clouds in the winter can lead to significant changes in surface cooling (Stephens et al., 1990). Given the important radiative influence of ice crystal size and COD it is necessary that these parameters are well characterized in order to improve modeling of their radiative effects (Ebert and Curry, 1992) and thus their influence within a context of TIC1 and TIC2 clouds.

The effective diameter of atmospheric ice particles is defined by Hansen and Travis (1974):

$$D_{\text{eff}} = \frac{3V}{2A}, \quad (1)$$

where  $A$  and  $V$  are respectively the total projected area and volume of all ice particles per unit surface area in a given atmospheric column (Baum et al., 2014). COD is given by

$$\text{COD} = \int \pi Q_{\text{ext}} \frac{D^2}{4} a(D) dD, \quad (2)$$

where  $Q_{\text{ext}}$  is the extinction efficiency (extinction cross section per unit projected-particle area; Hansen and Travis, 1974),  $D$  is the particle diameter and  $a(D)$  is the ice particle number density per unit increment in diameter. We note that, while the lidar-derived CODs employed in this article are at

0.532  $\mu\text{m}$ , the IR CODs from our retrieval method were referenced, for convenience, to 0.55  $\mu\text{m}$  (we assume that COD differences between 0.532 and 0.55  $\mu\text{m}$  are negligible within the context of other uncertainties encountered in this study).

### 3 Study site and instrumentation

The observation site was the Polar Environment Atmospheric Research Laboratory (PEARL) in Eureka, Nunavut (80° N, 86° W) which is one of the high-latitude stations of the Network for the Detection of Atmospheric Composition Change (NDACC, [http://www.ndsc.ncep.noaa.gov/sites/stat\\_reps/eureka/](http://www.ndsc.ncep.noaa.gov/sites/stat_reps/eureka/)). This high-Arctic site is located in the northernmost part of the Canadian Arctic Archipelago. It was chosen because of our interest in Arctic ice clouds and to exploit the diverse and complementary inventory of atmospheric instruments listed in Table 1 (i.e., lidar, radar, IR spectrometer and radiosondes), as well as the infrastructure and logistics support for field campaigns.

Detailed descriptions of the AHSRL and MMCR data processing and interpretative techniques can be found in Eloranta (2005) and Moran et al. (1998). A summary of instrument specifications is given in Bourdages et al. (2009). Knuteson et al. (2004a, b) present a discussion of the AERI performance which is applicable to the present paper. The AERI instrument is known to have a very small warm bias for low-radiance measurements, typically for clear-sky events, of the order of 1 % of the ambient radiance (Knuteson et al., 2004b; Delamere et al., 2010). As the focus of our work is on clouds with COD greater than 0.1, this warm bias in the AERI has only a slight to negligible impact for retrievals involving very thin clouds (Turner, 2003). The AERI data used in this work have been postprocessed to reduce the uncorrelated random error in the data using principal component analysis (Turner et al., 2006).

In this paper, we focus on the potential of using data from a ground-based multiband thermal radiometer, the CIMEL CE-312 developed by CIMEL Inc (see Legrand et al., 2000; Brogniez et al., 2003, for descriptions of a similar instrument). The six channels of this radiometer correspond to (full width at half maximum) limits of 8.2–8.6, 8.5–8.9, 8.9–9.3, 10.2–10.9, 10.9–11.7 and 11.8–13.2  $\mu\text{m}$  and filter response peak values at 8.4, 8.7, 9.2, 10.7, 11.3 and 12.7  $\mu\text{m}$ . The multiband radiometer is also a robust instrument that, unlike the AERI, does not require a thermally controlled environment. In actual fact, however, we had to simulate the response of this radiometer by convolving the spectral transmittance of each filter with the spectra of the Eureka Polar AERI (P-AERI) instrument (provided by Von Walden at the U. of Idaho and NOAA). The reason for this was that the CIMEL radiometer that we hoped to use was not ready for deployment when we performed the field campaigns.

Ground-based instrument	Duty cycle	Research group or institution
AHSRL (Arctic High Spectral Resolution Lidar)	Continuous	SEARCH/NOAA – University of Wisconsin–Madison
MMCR (Millimeter Cloud Radar)	Continuous	SEARCH/NOAA – ARM
Radiosonde	Twice a day	Environment Canada
P-AERI (Polar-AERI)	Continuous (except during precipitation)	SEARCH/NOAA – University of Idaho

4 Sensitivity of thermal infrared radiometry to thin ice clouds

The spectral sensitivity of longwave (thermal) radiation to the microphysical properties of ice clouds has been investigated for satellite data (Chiriaco et al., 2004; Dubuisson et al., 2008), airborne data (Brogniez et al., 2004; Libois et al., 2016) and ground-based sensors (e.g. Comstock and Sassen, 2001; Yang et al., 2005, and articles cited above). Previous studies have demonstrated that thermal IR radiometry is relevant in terms of permitting the retrieval of both COD and, to a degree,  $D_{\text{eff}}$ . The retrieval of the latter parameter permits, in turn, a discrimination of TIC1 and TIC2 clouds. The dependence of thermal IR radiometry on ice particle size is represented by Eq. (2). The extinction efficiency, a measure of particle attenuation (absorption and scattering), depends on particle size, composition and shape as well as wavelength (Hansen and Travis, 1974). It is common, in the case of zenith-looking thermal IR (8–14  $\mu\text{m}$ ) radiometry of ice clouds, to neglect the scattering portion of

$Q_{\text{ext}}$  (where  $Q_{\text{ext}} = Q_{\text{abs}} + Q_{\text{sca}}$ ), especially for large particles (Platt, 1973). The result in the presence of a medium such as cloud is extremely simplified radiative transfer that is characterized by a strong forward-scattering phase function: in the limit of a delta-function phase function, all forward-scattered radiation in any given direction of incidence is returned to the incident beam and the only radiance loss is due to absorption (see, for example, the delta-function irradiance solution of Meador and Weaver, 1980). Platt (1973) and later authors such as Turner and Löhnert (2014) indicated that only a small fraction of the zenith-looking downwelling radiation emitted by a cloud was due to scattering (in spite of the fact that  $Q_{\text{sca}} \approx Q_{\text{abs}}$ ).

We accordingly chose to plot absorption efficiency spectra in Fig. 2 in order to illustrate the spectral sensitivity of this key radiative transfer parameter. The absorption efficiency of TIC1 particles ( $D_{\text{eff}}$  from 10 to 30  $\mu\text{m}$ ) and TIC2 particles ( $D_{\text{eff}}$  from 35 to 120  $\mu\text{m}$ ) for “severely roughened solid column”-type crystals (Fig. 2a and b) were obtained from calculations reported by Yang et al. (2013) and Baum

**Figure 2.** (a, b) Absorption efficiency spectra for TIC1 and TIC2 particles across a range of  $D_{\text{eff}}$  values. (c) Mean absorption efficiency and standard deviations across the spectra of (a) and (b). The triangular symbols represent the integration of the absorption efficiency across the six bands of the CIMEL CE-312. These efficiencies were derived for the “severely roughened solid column”-type crystals of Yang et al. (2013) and Baum et al. (2014), available at [http://www.ssec.wisc.edu/ice\\_models/polarization.html](http://www.ssec.wisc.edu/ice_models/polarization.html).

et al. (2014). These spectra were then replaced by their mean and standard deviation over the two (TIC1 and TIC2)  $D_{\text{eff}}$  regimes in order to better appreciate the band to band separability of the TIC1 and TIC2 size classes (Fig. 2c). Prior to computing those means and standard deviations of Fig. 2c, we integrated the individual spectra of Fig. 2a and b across the pass bands of the six channels employed in this study (triangles in Fig. 2c). The  $D_{\text{eff}}$  ranges employed to define TIC1/TIC2 particles, for the averaging carried out in the creation of Fig. 2c, were, as in Grenier et al. (2009), roughly based on their nondetectability to detectability threshold in radar backscatter returns.

This coarse spectral representation obtained for the six band averages and standard deviations enables one to better appreciate the more robust nuances between the two families of spectral curves (especially for the 8.4, 8.7, 9.2 and 12.7  $\mu\text{m}$  channels) and better understand the key discriminatory elements of the classification into TIC1 and TIC2 clouds. It is clear from Fig. 2c that the first four bands offer the great-

est potential for discriminating particle size. Figure 2a and b, however, indicate a decreasing sensitivity to increasing particle size as one approaches  $D_{\text{eff}}$  values in the tens of micrometers.

We simulated the influence of COD and  $D_{\text{eff}}$  variations, on brightness temperature ( $T_b$ ) variations using the MODTRAN 4 radiative transfer model (Berk et al., 1999). Figure 3 shows simulated  $T_b$  variations for the six radiometer channels as a function of COD for fixed  $D_{\text{eff}}$  and as a function of  $D_{\text{eff}}$  for fixed COD. The fixed values of  $D_{\text{eff}}$  and COD (and other independent parameters of the MODTRAN 4 runs) correspond to a reference case with parameters that are defined in Table 2. We chose the input parameters of the reference case as the set of mean parameters obtained by averaging over the parameters of the 150 cloud cases that we employed to provide an empirical validation of our retrieval (see Sect. 6.2 and Table 2 for more details). The curves of Fig. 3 represent an illustrative subset of our inversion lookup table (LUT) that we employed as a means of retrieving COD and  $D_{\text{eff}}$  from

measured values of  $T_b$ . The  $D_{\text{eff}}$  column is biased by the fact that the lidar–radar retrieval is insensitive to TIC1 particles: the  $D_{\text{eff}}$  reference value was accordingly biased downward to roughly overcome this insensitivity. The value of  $50\text{ }\mu\text{m}$  was also the value employed by Sourdeval et al. (2013).

Figure 3a indicates that, at a fixed  $D_{\text{eff}}$  value of  $50\text{ }\mu\text{m}$ , there is a strong and monotonic variation in  $T_b$  as a function of COD for all channels. At COD magnitudes greater than 2–3, the  $T_b$  values for all channels converge towards an asymptotic ceiling that is the brightness temperature of an opaque representation of the cloud. This clearly shows that the sensitivity of the method decreases progressively as the COD increases beyond 3.

Differences in  $T_b$  behavior over a range of  $D_{\text{eff}}$  values and a fixed COD of 0.5 can be observed in Fig. 3b. For the channels of nominal wavelength less than  $10.7\text{ }\mu\text{m}$ ,  $T_b$  varies monotonically with  $D_{\text{eff}}$  up to approximately  $30\text{ }\mu\text{m}$ , after which the response plateaus to variations of  $\approx 1\text{ K}$  or less. For the  $11.3$  and  $12.7\text{ }\mu\text{m}$  channels, the responses are non-monotonic (or considerably less monotonic) for the smaller values of  $D_{\text{eff}}$  and smoothly decrease with increasing  $D_{\text{eff}}$  beyond a peak in the  $10$ – $20\text{ }\mu\text{m}$  range. This decrease is associated with the relatively large spectral changes seen in the refractive index of ice particles at these larger wavelengths (see, for example, Warren and Brandt, 2008).

As discussed above, IR radiance measurements are sensitive to a variety of cloud parameters as well as to the cloud environment. The simulation results in Fig. 4 detail the band-dependent effects of six different parameters by comparing changes in  $T_b$  induced by each parameter individually. These were obtained for 1000 appropriately normalized samples of a random number generator with a normal probability distribution, the mean and standard deviation of which was controlled by the six parameter values of Table 2 (COD,  $D_{\text{eff}}$ , cloud base height, cloud thickness, column-integrated water vapor of the atmosphere, WVC, and particle shape). The particle shape parameter is based on three particle characterizations as defined by Baum et al. (2014): severely roughened solid columns, a general habit mixture involving a set of nine habits and severely roughened aggregate of solid columns. The standard deviations in  $T_b$  that result from the variation of the six parameters are computed relative to the reference case defined above (Table 2). We note that there was little sensitivity to the choice of a  $50\text{ }\mu\text{m}$  effective diameter for the reference case: changing this typical TIC2 value to a value more representative of TIC1 particles produced differences of less than  $1\text{ K}$  in Fig. 4.

Figure 4 shows that the chosen COD variation had the strongest  $T_b$  influence of all of the parameters, especially for the bands at  $10.7$  and  $11.3\text{ }\mu\text{m}$  (as one could infer by referring to Fig. 3a). Changes in  $D_{\text{eff}}$  (in red) lead to a standard deviation around  $2\text{ K}$  for the four first bands as can be qualitatively appreciated by referring to Fig. 3b. Changes in the altitude of the cloud induce a standard deviation up to  $5\text{ K}$ . Indeed, because measurements of thermal IR radiometry are

sensitive to temperature, a change in altitude causes a  $T_b$  difference that is sensitive to the range of temperatures within which the cloud is located. Cloud thickness and WVC are marginally important parameters in terms of the magnitude of the changes induced in  $T_b$ . If the altitude and the thickness of the clouds are known from vertical lidar (and radar) profiles, then the magnitude of the altitude and cloud thickness uncertainties of Fig. 4 will fall to levels commensurate with the standard deviations ascribed to the uncertainty in the ice particle shape ( $\approx 1\text{ K}$  as per the dark blue curve). This latter uncertainty (determined from the habit parameterizations listed in Table 2) is largely inflexible inasmuch as our ability to distinguish ice particle shape from lidar depolarization data is extremely limited. Water vapor content (WVC) in the atmosphere, which remains relatively low during the polar winter at Eureka, has a weak absorption influence on the radiance measurements acquired in the CE-312 bands. Its associated uncertainty is commensurate with the uncertainties due to particle shape and cloud thickness: however integrated WVC is estimated from radiosonde profiles at Eureka and thus its uncertainty can be reduced to levels significantly below the particle shape and cloud thickness uncertainties. These reductions in the uncertainty of nominally known input parameters will be such that the variability of the parameters to be inverted (COD and  $D_{\text{eff}}$ ) is significantly larger than the uncertainty of the known input parameters (for all bands in the case of the COD and at least in the case of the first four bands for  $D_{\text{eff}}$ ).

## 5 Methodology

Our LIRAD objective was performed using LUTs and MODTRAN 4 radiative transfer simulations to parameterize the behavior of the downwelling zenith sky radiance as a function of key input parameters, including COD and  $D_{\text{eff}}$ . The methodology is represented in the flow chart of Fig. 5. The core of this method, inspired by ground-based retrievals (e.g. Turner, 2005), is to compare thermal IR radiance measurements with LUTs derived from MODTRAN 4 simulations. This inverse problem is solved using the optimal estimation method (OEM; Rodgers, 2000). The method seeks the state of maximal probability, conditional on the value of the measurements, associated errors and a priori knowledge. This OEM is an efficient inversion method that has already been employed for ice cloud retrievals (see, for example, Sourdeval et al., 2013).

The steps of the retrieval method are as follows:

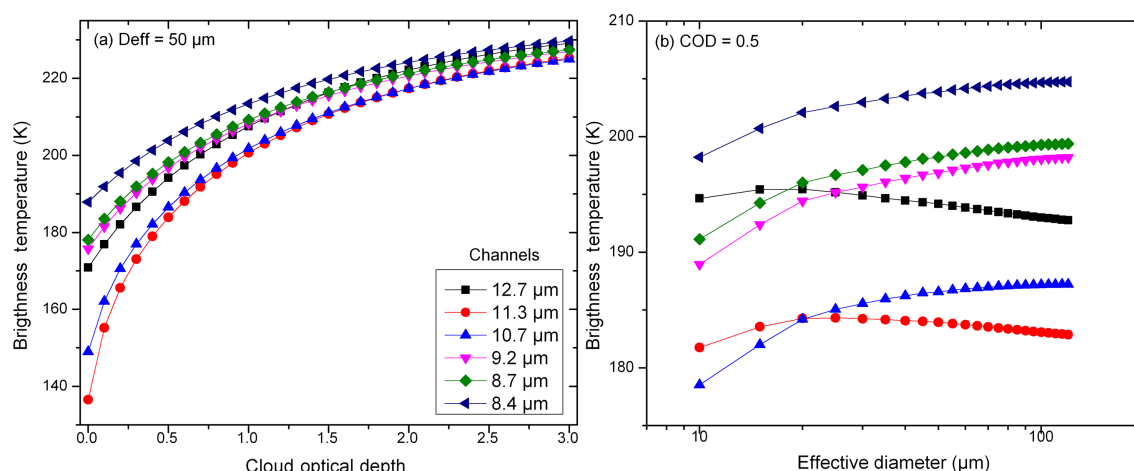

1. First, knowledge of the cloud environment at the time of a given radiometer measurement is required. Specific input auxiliary data includes pressure, temperature and water vapor profiles from radiosonde data and the effective cloud layer height from lidar backscatter data. The radiosonde parameters are interpolated to the radiometer times while the time of the selected lidar pro-

**Table 2.** Average, standard deviation, maximum and minimum values of the parameters of the cloud cases used in this study. The reference case, defined in the last row, was employed to produce Fig. 3 (while varying  $D_{\text{eff}}$  and the COD) and was used for the sensitivity study of Fig. 4. The means, standard deviations and extrema of each parameter were derived from our analysis of the 150 cloud cases. For the reference case, the cloud base height and thickness values were, for the sake of convenience, rounded to the nearest incremental step of the MODTRAN vertical layer profiles.

	Cloud base height (km)	Thickness (km)	Water vapor content ( $\text{g cm}^{-2}$ )	COD (lidar)	Deff ( $\mu\text{m}$ ) (lidar–radar)	Ice particle shape (three sets of models)
Average	5.19	2.30	0.19	0.46	91.06	Solid columns
Standard deviation	2.05	1.62	0.09	0.48	25.16	Aggregate of solid columns
Max	9.00	8.00	0.85	2.60	158.26	A mixture involving a set
Min	0.80	0.20	0.08	0.10	40.07	of nine habits
Reference case	5.20	2.20	0.19	0.50	50.00	Solid columns

A full description of the models can be found at [http://www.ssec.wisc.edu/ice\\_models/polarization.html](http://www.ssec.wisc.edu/ice_models/polarization.html).

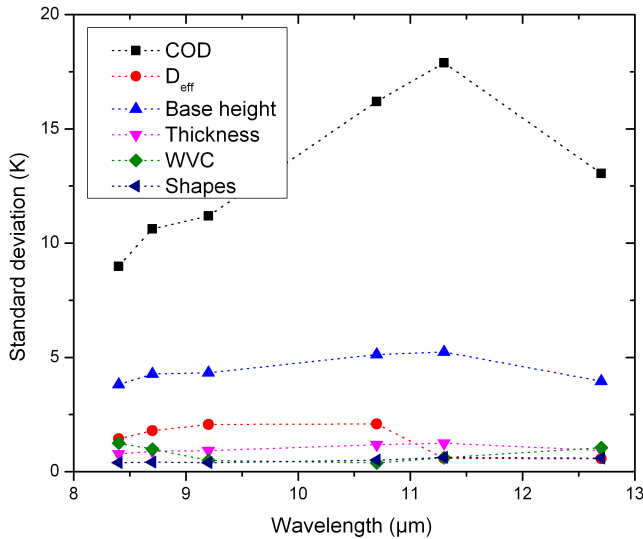

**Figure 3.** Variation in brightness temperature ( $T_b$ ) with (a) cloud optical depth (COD) and (b) effective diameter ( $D_{\text{eff}}$ ) for the six bands of the CIMEL CE-312. The color legend of the left graph applies to both graphs. The MODTRAN input parameters for this reference case are detailed in Table 2.

file is the nearest to the radiometer time. To avoid the issue of interpolating radiosondes over extensively long periods of time, the cases were selected to be as close as possible to radiosonde launch times. Radiosonde humidity sensors are known to be subject to dry bias, especially in dry conditions and could yield relative humidity underestimates of 10 % (Rowe et al., 2008). The six channels are, however, far less sensitive to WVC than to COD (see Fig. 4) and therefore the bias is expected to be lower in cloudy conditions. Cloud heights are estimated for sustained cloud features where clouds are defined by lidar backscatter coefficients greater than  $1.10^{-6} \text{ m}^{-1} \text{ sr}^{-1}$  and a lidar depolarization ratio greater than 20 % (thresholds were inspired by Shupe (2007) but adapted to a different vertical resolution of our lidar). Upper and lower cloud boundaries are then obtained where four continuous vertical samples of the lidar profile ( $4 \times 30 = 120 \text{ m}$  for an AHSRL resolution

of 30 m) comply with that requirement (preceded by a series of lower, noncloud samples).

- Using MODTRAN 4, we simulated surface-based zenith-looking brightness temperatures of a cloudy atmosphere as a function of the environmental data. A LUT is then constructed for 23 values of  $D_{\text{eff}}$  between 10 and  $120 \mu\text{m}$  and 31 values of COD (from 0 to 3 with an increment of 0.1). Because  $T_b$  is so strongly dependent on COD, the LUT is linearly interpolated between MODTRAN 4 calculations with a COD increment of 0.01.
- Brightness temperatures are then derived from radiance measurements in the six CIMEL CE-312 radiometer channels extracted from band-integrated P-AERI spectra.
- The OEM was used to compare the LUT spectra with the measured  $T_b$  spectra. This method requires precise

**Figure 4.** Sensitivity of  $T_b$  as a function of six key radiative transfer parameters. The standard deviations (in units of K) are obtained by stochastically varying, with a sample size of 1000, the parameters of interest within the limits given in the Table 2.

quantification of errors attributed to each variable of the state and measurement vectors (as detailed in Rodgers, 2000, and in Appendix A). We retrieve the best estimates of COD and  $D_{\text{eff}}$  from the most optimal fit to the measured  $T_b$ .

Specific validation elements for our retrieval algorithm included profiles of the effective ice particle diameter prime ( $D'_{\text{eff}}$ ) that were extracted from the combination of AHSRL and MMCR backscatter coefficients. This was carried out as per the technique developed by Donovan and van Lammeren (2001) and applied to the instruments at our study site (Eloranta et al., 2007).  $D'_{\text{eff}}$  is given by

$$D'_{\text{eff}} = \sqrt[4]{\frac{\beta_{\text{radar}}}{\beta_{\text{lidar}}}}, \quad (3)$$

where  $\beta_{\text{radar}}$  and  $\beta_{\text{lidar}}$  are the extinction cross sections of the radar and lidar respectively.  $D'_{\text{eff}}$  can be related to  $D_{\text{eff}}$  assuming an analytical form for the size distribution which in our case was taken as a modified gamma distribution of hexagonal columns (Eloranta et al., 2007). In order to compare  $D_{\text{eff}}$  with our retrievals, we averaged this parameter over the vertical extent of a given cloud. We chose, for simplicity's sake, to assume a specific particle shape (i.e., the hexagonal column shape) when retrieving  $D_{\text{eff}}$  from the lidar/radar profiles to enable consistent comparisons with our passive retrievals. As a general quality assurance step for the radar data, those cases for which the radar backscatter coefficient was less than  $10^{-15} \text{ m}^{-1} \text{ sr}^{-1}$  (an empirically determined value of minimum detectability) were eliminated from any retrieval processing (this generally meant the elim-

ination of TIC1 points). It is also important to state that radar signal is proportional to the sixth power of the hydrometeor diameter, whereas IR instruments are sensitive to the ratio of the third to the second moment. This means that the equivalent  $D_{\text{eff}}$  is not strictly the same and their comparison can generate biases in some conditions (see discussion in Turner, 2005).

The CODs from the passive algorithm was validated by comparison with estimates of COD derived from AHSRL observations using Eq. (4) and averaged over the cloud geometric thickness. By its design, the AHSRL measures two signals which can be processed to yield separate lidar returns for aerosol and molecular scattering, and then to make reliable measurements of the extinction profile. The optical depth  $\tau$  across a range interval ( $r, r_0$ ) is computed as

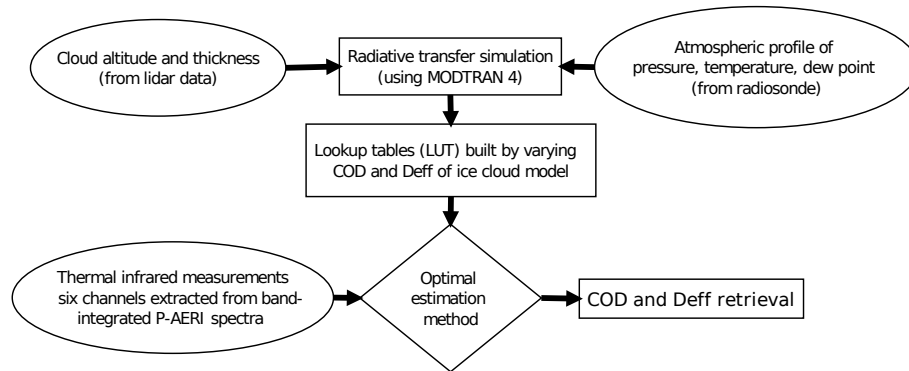

$$\tau(r) - \tau(r_0) = \frac{1}{2} \ln \left( \frac{\rho(r)}{\rho(r_0)} \right) - \frac{1}{2} \ln \left( \frac{S_m(r)}{S_m(r_0)} \right), \quad (4)$$

where  $\rho$  is the molecular density, and  $S_m$  is the range-squared, background-corrected, molecular lidar return of the AHSRL. COD was calculated, using Eq. (4), across the cloud layer where the vertical cloud boundaries were determined according to the backscatter coefficient and depolarization criteria described above. Due to the very small angular field of view of the AHSRL receiver ( $45 \mu\text{rad}$ ), it is common to assume that the backscatter return is negligibly affected by multiple-scattered photons (Eloranta et al., 2007). However, to better quantify the effect of multiple scattering, we applied Eloranta's (1998) approximate model to calculate the multiply scattered lidar returns for the 150 cloud cases. The inputs included molecular and particulate backscatter coefficients, effective diameters (inferred from the AHSRL+MMCR technique discussed below) and cloud height boundaries. The approximate model was employed to compute multiple scattering returns up to the fourth order. The impact of multiple scattering (MS) can then be evaluated in terms of COD inasmuch as multiple scattering lowers the apparent COD. From Eq. (4), we define  $\Delta\text{COD}_{\text{ms}}$  as

$$\Delta\text{COD}_{\text{ms}} = -0.5 \log(1.0 + \text{Pt}/P1), \quad (5)$$

where Pt is an output of the MS model, representing all orders of multiple scattering while P1 is the single-scattering return. This term can be used to correct the retrieved optical depth by inserting a multiplicative factor  $\eta$ , as per Platt (1973) to correct for the reduction of the extinction coefficient. The parameter  $\eta$  is not constant (Bissonnette, 2005) and Platt argued that it should vary between 0.5 and 1. Our best estimate of  $\eta$  over the ensemble of test cases was 0.95. This factor was used to correct the lidar-derived CODs that we employed for validation purposes in this paper.

Although intervals of P-AERI spectra (wavelength range of 3–20  $\mu\text{m}$ ) were used to simulate the response of the CIMEL radiometer bands, the P-AERI instrument has more extensive capabilities and is sensitive to a larger range of

**Figure 5.** Flow chart of the retrieval method.

$D_{\text{eff}}$ , according to the absorption efficiency spectra (see Fig. 2 in this article or Fig. 5 in Yang et al., 2003). The mixed-phase cloud retrieval algorithm (MIXCRA; Turner, 2005) is designed to estimate microphysical properties of both the ice and liquid components of a cloud using spectral IR radiances supplemented with data from various instruments. By using the spectral behavior of several “microwindows” between gaseous absorption lines in the thermal and far IR, MIXCRA can determine cloud phase and retrieve COD and  $D_{\text{eff}}$  (a detailed description of the algorithm can be found in Turner, 2005). Turner and Eloranta (2008) have demonstrated good agreement between the MIXCRA retrievals and HSRL optical depth measurements during an experiment at the ARM NSA site. Cox et al. (2014) describe the specifics of the Eureka implementation, including the auxiliary measurements that were employed (notably the AHSRL, MMCR, radiosonde data and a microwave radiometer). Within the scope of this current study, the cloud-phase determination from MIXCRA is used to ensure the comparison of ice-only cloud properties (i.e., those MIXCRA retrievals that yielded negligible liquid water path,  $LWP < 0.2 \text{ g m}^{-2}$ , were taken as being pure ice-cloud cases). MIXCRA results are used here as an alternative point of reference for our retrievals.

## 6 Results and discussion

### 6.1 Physical coherence of a specific case study

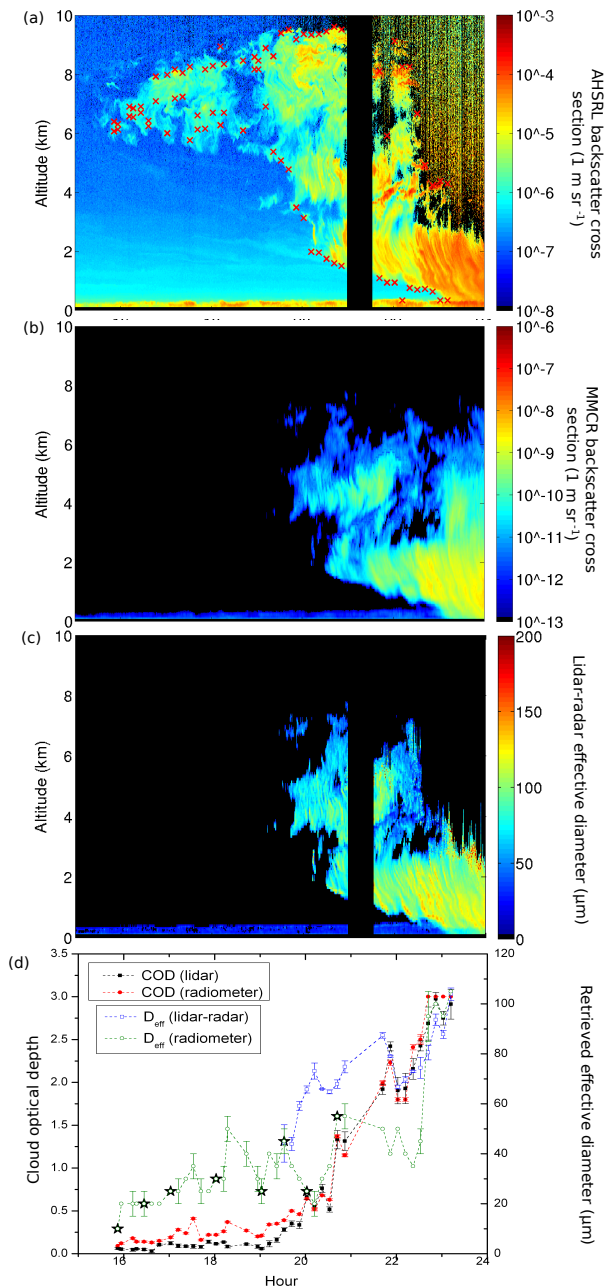

In this section we seek to illustrate the temporal variation of particle size and COD in a precipitating cloud and demonstrate that our retrieval gives physically coherent results for a specific case that was chosen to exercise both the COD and  $D_{\text{eff}}$  retrievals. Figure 6 shows the selected 2009 winter campaign case where we compare AHSRL backscatter coefficient, the MMCR backscatter coefficient profile, the  $D_{\text{eff}}$  profile (which, as pointed out above, is related to  $D'_{\text{eff}}$ ) and the results of our inversion (Fig. 6a, b, c and d respectively).

Radar reflectivity is commonly used to describe the reflection, scattering and diffraction effects of a target on the in-

cident signal. Radar reflectivity, expressed in dBZ, is logarithmically proportional to the backscatter coefficient and is proportional to the sixth power of the hydrometeors diameter (Battán, 1973). However, to ensure a consistent approach within the context of  $D_{\text{eff}}$  retrieval, we chose to display  $\beta_{\text{radar}}$  in Fig. 6b.

One can see (Fig. 6d) that  $D_{\text{eff}}$ , for the lidar–radar technique (in blue), increases from 44 to 103  $\mu\text{m}$ . This increase appears, in turn, to be correlated with cloud precipitation as evidenced by the accompanying decrease in altitude of the cloud structure seen in the lidar and radar profiles as well as increasing values of the radar Doppler fall velocity profiles (not shown). The passive  $D_{\text{eff}}$  retrievals (the green colored curve of Fig. 6d) show a roughly similar trend from 20:00 to 23:00 (largely characterized, however, by significantly smaller  $D_{\text{eff}}$  values). The insensitivity of the latter retrieval to larger size particles during the period from about 19:00 to 22:30 and the sudden jump in retrieved  $D_{\text{eff}}$  value after that time is the result of the type of asymptotic ceiling that one sees in Fig. 3b and the choices made in the LUT algorithm retrieval: as one approaches the asymptotic ceiling from smaller  $D_{\text{eff}}$  values, there is clearly a progressive increase in the range of acceptable  $D_{\text{eff}}$  values for a given  $\Delta T_b$  (a decrease in the robustness of the retrieved value). This example also illustrates an important issue related to our TIC1/TIC2 classification goal, for which some points, around 20:00 appear to be classified as TIC1 particles by our algorithm while the lidar–radar values between 60 and 80  $\mu\text{m}$  would be classified as TIC2 particles. One possible explanation is that the cloud vertical inhomogeneity, as evident in the cloud structure observable in Fig. 6a is the source of the misclassification. The regions of the effective diameter that are not detected by the lidar–radar retrieval (see the profiles of Fig. 6c) are indeed optically thick regions with more impact on the radiometric retrieval of Fig. 6d and likely contain smaller particles.

The COD retrievals are, as one would expect, visually coherent with the general strength and extent of the lidar backscatter coefficient. After 23:00 UTC our COD retrievals

**Figure 6.** Evolution of validation and retrieval cloud parameters during a particular precipitating cloud event (13 January 2009) at Eureka. The error bars of the bottommost graph represent the retrieval errors. The error for the lidar COD retrievals is sufficiently small to be obscured by the size of the symbols representing this component. The red crosses in the uppermost plot are the cloud boundary limits used as input to our method. The points upon which a star has been superimposed satisfied the criteria defined at the beginning of Sect. 6.2 and are thus an example of points accepted in the validation part of this article.

approach the limit of retrieval sensitivity suggested in Fig. 3. This is manifested by an artificial nonmonotonic increase in the variability of the retrieved COD (not very obvious in Fig. 6 but obvious from our inversions in general) and is coherent with the asymptotic invariance of  $T_b$  with increasing COD in Fig. 3.

This example suggests that the dynamic evolution of cloud particle properties provided by continuous temporal analysis can lend support in helping to understand cloud dynamics and more specifically in discriminating TIC1 and TIC2 particles. In the latter case the passively retrieved evidence for progressively increasing values of COD and  $D_{\text{eff}}$ , supported by the lidar and radar data, would lend more confidence to a classification result which indicated the presence of TIC2-type particles during the latter part of the day.

## 6.2 Validation of our retrieval algorithm

Figure 7 shows COD and  $D_{\text{eff}}$  comparisons between the radiometric retrievals and the combined AHSRL and MMCR retrievals for over 150 ice clouds observed between September 2006 and March 2009. The selection of the 150 cases was driven by different criteria: a requirement for monolayer clouds; a cloud thickness greater than 200 m (to equal or exceed the MODTRAN vertical layer thickness of 200 m); the time difference between two samples was more than 30 min; the clouds were nonprecipitating; a subjective criterion of cloud homogeneity; a constraint whereby the evidence for cases of TIC1 only, TIC2 only or a combination of the two was determined by whether the cloud was detected by the lidar and the radar; a requirement that the cloud is semitransparent (AHSRL optical depth  $< 3$ ); a constraint that the IR signal in any band is not saturated; the visible optical depth should be greater than 0.1 and the visible optical depth across the first two kilometers (where diamond dust particles are very often present in winter) should be less than 0.1. As an illustration of the influence of these criteria, only 8 of the 41 points seen in Fig. 6 were selected to be part of the 150 cases.

Those clouds are not meant to be representative of the Eureka cloud climatology. Their mean base altitude (5.2 km) and vertical extent (2.3 km) is substantially higher than a cloud climatology that was generated across 4 years of data (Shupe et al., 2011; 1.8 and 2 km respectively) as well as the CALIPSO/CloudSat and ground-based climatologies on the vertical distribution of ice-only cloud (Blanchard et al., 2014).

The COD results (Fig. 7a) show a significant correlation with lidar ( $R^2 = 0.95$ ) over a large optical depth range (from 0.1 to 2.6). This level of agreement confirms the relatively strong sensitivity of the ensemble of the radiometer bands to the COD (c.f. Fig. 3a). As seen in that figure, the  $T_b$  sensitivity decreases with increasing COD such that the asymptotic behavior of the COD variation tends towards an upper limit of COD detectability of 2–3 (where the spread of  $T_b$  values  $\approx$  the measured uncertainty in those  $T_b$  values).

**Figure 7.** Radiometer-based retrieval results for (a) CODs compared with lidar derived CODs and (b)  $D_{eff}$  compared with the lidar–radar retrieval product. The same comparisons, with MIXCRA retrievals being the reference, are shown in graphs (c) and (d). The TIC1 results, because of the lidar–radar insensitivity of these small particles, are excluded from the scattergram but their  $D_{eff}$  frequency distribution is shown in the inlaid histogram. The  $D_{eff}$  comparisons with the MIXCRA retrievals show fewer points than the comparisons with the lidar–radar retrieval because the MIXCRA retrievals of  $D_{eff}$  have relatively large uncertainties for cases where  $COD \leq 0.2$  (and thus are not shown).

**Table 3.** Confusion matrix of the TIC1/TIC2 classification compared to lidar–radar retrievals. The term “err. comm.” stands for the error of commission.

		Lidar–radar	
		TIC1 (no.: 50) ( $D_{eff} \leq 30 \mu m$ )	TIC2 (no.: 100) ( $D_{eff} > 30 \mu m$ )
no. of observation: 150			
Radiometer	TIC1	39	15
	TIC2	11	85
Overall accuracy = 83 %		err. comm. TIC1 = 22 %	err. comm. TIC2 = 15 %

The quality of the particle size retrieval was difficult to quantify because the thermal IR channels become increasingly less sensitive to particles larger than  $\approx 100 \mu m$  as suggested in Fig. 2b. This insensitivity to large particle sizes likely contributes to the large dispersion (and hence the marginal correlation) of retrieved TIC2 values seen in Fig. 7b. The separation between TIC1 and TIC2 particles was affected based on the  $D_{eff}$  values from the lidar–radar retrieval: the lower bound TIC2 value/upper bound TIC1 value was set at  $30 \mu m$ . We show below that while the radiome-

ter  $D_{eff}$  retrievals are of significantly lower amplitude than the lidar–radar retrievals, the  $30 \mu m$  crossover criterion from TIC1 to TIC2 is sufficiently well delineated to achieve acceptable classification accuracy. One factor that complicated the  $D_{eff}$  comparison over all particles sizes was the MMCR sensitivity limit at smaller particle sizes ( $\approx 30\text{--}40 \mu m$ ) and the constraints this imposed on the lidar–radar retrieval. For that reason, the TIC1 results were not considered in the  $R^2$  statistics. However, the TIC1 frequency distribution derived for our retrieval algorithm (inlaid histogram in Fig. 7b) con-

firms the robustness of the retrievals inasmuch as 78 % of the retrieved TIC1 population have a  $D_{\text{eff}}$  less than  $30\text{ }\mu\text{m}$  (and 96 % less or equal to  $50\text{ }\mu\text{m}$ ).

The lack of TIC1 sensitivity of the lidar–radar combination means that our radiometric retrieval algorithm cannot be verified with the lidar–radar retrieval in the TIC1 particle-size region. Nonetheless, the lidar–radar classification scheme of Sect. 3 can at least separate out the TIC1 and TIC2 cases. Table 3 presents the retrieved results in terms of the TIC1/TIC2 classification compared with the validation data. A threshold value of  $30\text{ }\mu\text{m}$  was used to discriminate between the two classes in the case of the radiometer retrieval. Those cases for which  $\beta_{\text{radar}}$  was less than  $10^{-15}\text{ m}^{-1}\text{ sr}^{-1}$  were classified as TIC1 cloud (this cutoff is illustrated by the dark regions of the  $\beta_{\text{radar}}$  plot seen in the case study of Fig. 6). The classification yielded satisfactory results with an overall accuracy of 83 %. The TIC1 retrievals were associated with a 22 % detection (omission) error ( $11/50 \times 100$ ) while the TIC2 omission error was 15 %. We should note that the classification results are moderately sensitive to the threshold  $D_{\text{eff}}$  value assumed between the TIC1 and TIC2 classes: for threshold values of 35 and  $40\text{ }\mu\text{m}$ , the overall accuracies were respectively 82 and 82 % with moderately smaller TIC1 omission errors (18 and 12 % respectively).

A comparison with the MIXCRA retrievals (Fig. 7c and d and Table 4) amounts to a coherency check between the two passive inversion techniques. While limited in terms of absolute validation, this comparison effectively reduces the array of confounding influences that can affect the retrieval quality of both approaches (and in so doing, permits a more direct evaluation of the strengths and weaknesses of either technique). In Fig. 7c, the good correlation between MIXCRA's and our COD retrievals and a slope near 1 confirm the robustness of the COD retrieval. The good COD correlation is expected inasmuch as a similar degree of correlation between MIXCRA and AHSRL results for ice-only clouds was previously observed (Turner and Eloranta, 2008). The comparison of the  $D_{\text{eff}}$  values from our radiometer retrieval and the MIXCRA retrieval (Fig. 7d) shows a somewhat better absolute agreement relative to the comparisons of our radiometer retrieval with the lidar–radar retrieval (point scatter closer to  $y = x$  but a value of  $R^2$  which is also at the margins of significance).

Figure 8 indicates that all of cases with  $\text{COD} > 1$  were classified as TIC2 for the passive and active retrievals. Clouds classified as TIC1 are, in contrast, preferentially associated with COD less than 0.3. The degree of TIC1/TIC2 classification coherence between the lidar–radar and the radiometer retrievals, in the histogram of Fig. 8, illustrates the value of our semiquantitative (binary) classification approach for an application (the DGF effect of Blanchet and Girard, 1994) that specifically requires such binary information.

In order to better understand the physical implications of the retrievals, we plotted, in Fig. 9, passive TIC1/TIC2 discrimination results along with downwelling longwave cloud

**Figure 8.** Histogram of active and passive classifications of TIC (TIC1 in red and pink; TIC2 in blue and cyan) as a function of COD.

**Figure 9.** Downwelling longwave cloud radiative forcing of the 150 cases decomposed in TIC1 and TIC2.

radiative forcing (DLCRF). These data represent the 150 cloud cases that we employed above for the retrieval validation. The general distribution of the DLCRF is similar to the Fig. 4 results of Cox et al. (2014), who applied the MIXCRA algorithm continuously (without the separation into specific events) during the same period. As DLCRF is closely linked to the COD, one can note that the TIC1 generally have a small DLCRF of less than  $10\text{ W m}^{-2}$ . The DGF impact of the TIC2 particles (meaning their progressive removal by precipitation) would accordingly be that their radiative forcing influence would progressively decrease with an attendant cooling due to a reduction in thermal interaction with the remaining TIC1 particles (and the unprecipitated TIC2 particles). A long-term analysis would help to support modeling conclusions on the impact of acid-coated ice nuclei on Arctic cloud as reported by Girard et al. (2013). These authors reported

a mean downward longwave (negative) radiation anomaly at the surface of  $-3\text{--}5 \text{ W m}^{-2}$  close to Eureka.

### 6.3 Additional sensitivity studies

The effect of particle shape on the retrievals was analyzed by reapplying the retrieval algorithm to the 150 thin ice clouds using particle shapes other than our solid column crystal standard (not shown). Retrievals results showed that the shape employed in the LUT generation has only a small influence on the performance of our retrievals (as one could have inferred from Fig. 4). This confirms the previous conclusion from Wendisch et al. (2007). The validation of COD retrievals, expressed in terms of RMSE, varied from 0.10 to 0.11 as a function of shape while overall classification accuracy varied from 82 to 83 % (versus the results of 0.10 and 83 % respectively for the solid column crystal shape).

We exploited the extinction coefficient profile retrieval obtainable from Eq. (4) in order to evaluate the impact of the extinction profile as an added dimension of input to the radiative transfer model. Rather than assuming a constant extinction coefficient profile across the width of the cloud, we broke the cloud into vertical segments and obtained a coarse vertical profile. Retrieval results showed a moderate impact of the extinction profile since the RMSE is 0.09 instead of 0.10 while the overall classification accuracy remained at 83 %. A similar comparison from MIXCRA results (not shown here) confirms the moderate impact of the use of real extinction profiles.

## 7 Conclusions

We developed a simple inversion technique to retrieve the optical depth and effective particulate diameter of Arctic thin ice clouds from a multibroadband thermal radiometer using lidar and radiosonde measurements as auxiliary inputs to the inversion routine. Specific validation elements were extracted from the combination of lidar and radar data, as well as AERI data. Our retrieval technique was applied to 150 thin ice clouds measured at the PEARL observatory (Nunavut, Canada).

The results of this study demonstrate the potential for retrieving key ice cloud parameters from thermal IR radiometry (with bands between 8 and  $13 \mu\text{m}$ ). The COD retrieval algorithm showed good agreement with the validation COD obtained from integrated lidar profiles. The retrievals of  $D_{\text{eff}}$  showed a marginal correlation for particle sizes restricted to the TIC2 category (a constraint that was driven by the insensitivity of the lidar–radar retrievals to small cloud particles). This is likely due to the weak sensitivity of thermal IR measurements for particles larger than  $\approx 100 \mu\text{m}$ . However, a classification of thin ice clouds in terms of TIC1 and TIC2 classes, using a threshold discrimination of  $30 \mu\text{m}$  results in a significant classification accuracy of 83 % for our passive retrieval algorithm. Further analysis showed that the extinction profile and particle shape had a relatively weak impact on the retrieval results. Comparisons with the MIXCRA algorithm confirm the robustness of the optical depth retrieval.

An important application of our work would be to deploy this technique as part of a network of low-cost, robust instruments to monitor Arctic clouds. Because their occurrence, type and altitude are spatially inhomogeneous (according to Eastman and Warren, 2010; Shupe et al., 2011), we believe that additional ground-based stations would be helpful to broaden our knowledge of arctic ice clouds. Aside from being a ground-based retrieval approach in its own right (in tandem with a lidar system), this method can also be used for comparison with CALIPSO’s level 2 products. The CALIPSO remote sensing suite technique employs an on-board imaging IR radiometer and the CALIOP lidar to enable the retrieval of particle size and optical depth across a narrow swath image (Garnier et al., 2012). Our retrieval, viewed as a CALIPSO validation technique is rendered all the more interesting because of the geographic position of the PEARL site; it is a high-Arctic site that sees frequent thin-cloud events and its position near the maximum latitude of the CALIOP polar orbit ensures that there are frequent overpasses of that sensor package (within a radius of hundreds of kilometers).

*Data availability.* The data we used are accessible from the CANDAC server using SSH protocol. Registration to access CANDAC data can be done through the form (<http://candac.ca/candacweb/contact-us>) or by contacting CANDAC data manager Yan Tsehtik ([yan.tsehtik@candac.ca](mailto:yan.tsehtik@candac.ca)).

## Appendix A: Optimal estimation method

The optimal estimation method (OEM, Rodgers, 2000) is an efficient solution to inverse problems, especially in atmospheric science. A good understanding of the technique and its associated errors is a prerequisite for the proper use of this method. Inasmuch as our application of OEM is very similar to Sourdeval et al. (2013), we used the same formalism to define the OEM components. As set out in Sect. 5, the OEM goal is to retrieve state variables with the maximum probability of occurrence by minimizing a cost function  $\phi$ :

$$\phi = (y - F(x))^T S_e^{-1} (y - F(x)) + (x - x_a)^T S_a^{-1} (x - x_a), \quad (\text{A1})$$

where  $F$  is the forward model, i.e., radiative transfer computation in our case. The state ( $x$ ), a priori ( $x_a$ ) and measurement ( $y$ ) vectors are defined as

$$x = \begin{pmatrix} D_{\text{eff}} \\ \text{COD} \end{pmatrix}; x_a = \begin{pmatrix} D_{\text{eff}_a} \\ \text{COD}_a \end{pmatrix}; y = \begin{pmatrix} T_{b_{8.4}} \\ T_{b_{8.7}} \\ T_{b_{9.2}} \\ T_{b_{10.7}} \\ T_{b_{11.3}} \\ T_{b_{12.7}} \end{pmatrix}. \quad (\text{A2})$$

The a priori vector is the prior knowledge of the state vector, and typically corresponds to climatological values of the state vector components. In our case, the reference case of Table 2 was used to define the a priori vector and its covariance matrix. Even if any particular a priori vector values have an impact on the retrievals, it is common to attribute large uncertainties to them in the covariance matrix  $S_a$  in order to let the measurement vector be the dominant driver of the retrieval. This covariance matrix is given by

$$S_a = \begin{pmatrix} \sigma_{D_{\text{eff}_a}}^2 & 0 \\ 0 & \sigma_{\text{COD}_a}^2 \end{pmatrix}. \quad (\text{A3})$$

The total error covariance matrix  $S_e$  is the quadratic sum of the measurement error covariance matrix  $S_y$  and the forward model parameter uncertainty covariance matrix  $S_f$ . We assumed that the components of the measurement or state vectors are independent (i.e., that the covariance matrix is diagonal). The measurement errors depend on the accuracy of the radiometer (which is assumed to be 0.1 K for each band, Brogniez et al., 2003). We presumed the measurement errors are wavelength independent. The forward model errors represent the quadrature sum of the uncertainties of each input parameter (cloud base height, thickness, water vapor content and particle size) of the MODTRAN calculation. We then use the sensitivity study, Fig. 4, to define the standard error ( $\sigma/\sqrt{1000}$ ) of each parameter from the stochastic analysis. The components of  $S_e$  are close to 0.30 K (between 0.28 and 0.34 K) and of the same order of magnitude as  $S_y$ .
