Accepted Article

mechanisms driving management effects on soil ecosystem engineers is needed to support sustainable management under environmental change.

2. This paper presents the EEWorm (Energy – Environment – Earthworm) model, a mechanistic individual-based model (IBM) of *Lumbricus terrestris* populations. *L. terrestris* is a dominant earthworm species in undisturbed habitats and is closely associated with numerous ecosystem services such as water flow regulation, soil structure and crop production. In reduced tillage agriculture a decline in mechanical disturbance allows for *L. terrestris* proliferation, whilst the activities of *L. terrestris* can replace many of the soil functions provided by tillage.
3. Extensive EEWorm validation with eight published studies (average  $R^2 = 0.84$ ) demonstrates a mechanistic approach which can extrapolate between diverse soil, management and weather conditions. EEWorm simulation experiments elucidate that a combination of direct and indirect tillage effects lead to population declines in tilled fields, with litter removal from the soil surface being the main driver.
4. We investigate the effects of different tillage intensities under historical and projected soil warming conditions, and find that future warmer and drier soils in our simulation exacerbate the effects of deep ploughing on *L. terrestris* population declines. These effects result from warmer and drier soil conditions increasing individual metabolic rates and tillage reducing food availability to meet energy demands.
5. *Synthesis and applications.* Pre-emptive strategies to mitigate climate change impacts on soil health in agroecosystems should focus on decreasing tillage intensity and retention of crop residues following tillage. EEWorm has the potential to benefit land managers, policy makers, risk assessors and regulators by providing a tool to forecast how soil systems respond to combinations of land management and environmental change. To allow better cost-benefit analysis of contrasting land management systems a future aim of mechanistic models like EEWorm is to incorporate the links between earthworm populations, soil functions and ecosystem services.

**Keywords:** agriculture; earthworm; ecosystem engineer; environmental change; land management; *Lumbricus terrestris*; soil warming; tillage.

## INTRODUCTION

Soils benefit the human population by facilitating essential ecosystem services such as food production, climate regulation and nutrient cycling (Power 2010). Crucial for a growing human population are the foundations that soils provide for agriculture. However, tillage practices (e.g. moldboard ploughing) have led to extensive soil degradation, placing increasing pressure on ecosystem service delivery (Palm *et al.* 2014). To sustain ecosystem services in agriculture a shift in management is needed toward the biological regulation of ecosystem services by the soil biota (Bender, Wagg & van der Heijden 2016). Within soils, ecosystem engineers are important in facilitating the soil functions that underpin ecosystem services (Barrios 2007).

Earthworms have been identified as the most important ecosystem engineers in soils and are widely considered important bio-indicators of soil health (van Capelle, Schrader & Brunotte 2012). By burrowing through the soil, earthworms produce large pores that are important for water flow and retention, aeration, and root development. They help mix organic materials into the soil and aid in aggregate formation, whilst relationships with microorganisms play an essential role in nutrient cycling and organic matter decomposition (Kladivko 2001). Different earthworm species play different roles in soil functioning, which are reflected by their functional groups: epigeic, anecic or endogeic. Epigeics are litter transformers, mineralizing and digesting plant remains at the soil surface, anecics inhabit semi-permanent vertical burrows originating at the soil surface whilst endogeics form temporary horizontal burrows in the mineral soil (Bouché 1977).

Accepted Article

Anecic earthworms have been shown to increase crop yields and aboveground biomass (van Groenigen *et al.* 2014), water infiltration rates which reduce surface run-off associated with accelerating soil erosion and flooding (Andriuzzi *et al.* 2015), N mineralization from crop residues which promotes plant production (van Groenigen *et al.* 2014) and soil organic carbon (SOC) stocks which is closely associated with nutrient availability and plant quality (Shuster, Subler & McCoy 2001). However, anecic earthworm populations are significantly reduced in agricultural fields due to tillage (van Capelle, Schrader & Brunotte 2012). Climatic factors also moderate earthworm populations and can directly influence their response to tillage practices (Briones & Schmidt 2017). Understanding the mechanisms driving both tillage and climate effects on anecic earthworms is thus important in better informing sustainable agriculture in uncertain future conditions.

Tools are needed to better predict how combinations of land management and climate change scenarios affect the provision of ecosystem services from soils. Population models show promise for gaining insights into the feedbacks between populations, management and climate systems, but most are either not realistic or not flexible enough for wide scale application. Statistical models or models that project current situations are also little suited to extrapolation outside the range they are parameterised, and so may be unreliable for prediction under novel future conditions including environmental change (Urban *et al.* 2016). Mechanistic models which capture key biological, physiological and ecological mechanisms underpinning system functioning should have better predictive power (Evans, Norris & Benton 2012).

In this paper we present the EEEworm (Energy – Environment – Earthworm) model, a mechanistic individual-based model (IBM) of the anecic earthworm *Lumbricus terrestris* in the soil system. The model is developed from a previously published mechanistic model, which has demonstrated excellent predictive power for endogeic earthworms (Johnston *et al.* 2015). During model simulations, individual physiology and behaviour respond to trade-offs

in prevailing environmental conditions, and population dynamics emerge. Here, we validate EEWorm's ability to capture numerous patterns in *L. terrestris* life cycles and population dynamics in various environmental and management scenarios. We use model experiments to elucidate how tillage achieves its effects on *L. terrestris* populations, and apply EEWorm to forecast long-term population responses to different tillage intensities under soil warming conditions.

## MATERIALS AND METHODS

EEWorm builds on the same principles as previously published models of the epigeic earthworm *Eisenia fetida* and the endogeic earthworm *Aporrectodea caliginosa*, namely the combination of energy budgets and movement in response to trade-offs in environmental conditions (Johnston *et al.* 2014a; Johnston *et al.* 2014b; Johnston *et al.* 2015). Previous models proceeded in daily time-steps and represented 2D cross-sections of the soil surface for epigeic or the soil profile for endogeic earthworms, set up with 10 × 10 cm patches and species-specific energy budget parameters and behavioural rules. Here, EEWorm is adapted for the behavioural (e.g. burrowing) and physiological (e.g. life cycle) traits of the anecic earthworm *Lumbricus terrestris*, an important soil ecosystem engineer in no-till agriculture and natural ecosystems.

## MODEL OVERVIEW

EEWorm represents individual earthworms with their own energy budgets and behavioural decisions, interacting with each other and their environment in a spatially explicit IBM. The model environment represents a vertical cross-section of a soil profile, comprising 1 × 1 cm soil patches characterised by soil temperature, water content, texture, bulk density, soil organic matter (SOM) and plant litter quantity and quality inputs (Fig. 1). EEWorm proceeds in hourly time-steps here with a 12:12 hour day:night cycle. Daily and seasonal fluctuations in soil conditions (e.g. soil temperature, SOM, plant litter), are modelled according to

observed seasonal and vertical relationships (for further details see Johnston *et al.* (2014b) and Johnston *et al.* (2015) and Appendix S1 of the Supporting Information).

(Figure 1 here)

Individual energy budgets describe how individuals acquire energy from food and expend energy on life cycle processes in priority order: maintenance, reproduction, growth and energy storage (Fig. 1). Population dynamics then emerge from the collective activities of individuals and their interactions in heterogeneous soil environments. EEWorm model parameters are presented in Table 1, together with their units and sources. Additional model details are provided in Appendix S1 of the Supporting Information. The EEWorm model NetLogo program code developed by Alice Johnston is Copyright © 2017 University of Reading and licensed under the GNU General Public Licence version 3 (Appendix S2 of the Supporting Information).

(Table 1 here)

Individual behaviour is modelled according to individual life stage, size, energy status, and environmental and population density conditions. Inevitably, some of the complex behaviours exhibited by *L. terrestris* are simplified in the EEWorm model. A conceptual model of the behavioural decisions made by individuals in hourly time-steps are outlined in Fig. 2. Modelled behaviour is described in the following sections and further details are given in Appendix S1 of the Supporting Information.

(Figure 2 here)

**Form burrow.** If an individual does not already inhabit a burrow, it will prioritise energy expenditure to burrow formation above growth and reproduction. Potential new burrow sites

must leave a minimum distance of 20 cm between neighbouring burrows (Nuutinen & Butt 2005). If the population is space-limited, co-habitation of a single burrow can occur between a maximum of two adults, whilst cohabitation of a burrow between a parent and its juvenile offspring can occur at any time (Lowe & Butt 2002; Grigoropoulou, Butt & Lowe 2008). Burrows are modelled as vertical structures, running from the soil surface to deeper soil depths as in Fig. 1. The vertical elongation of a burrow depends on the occurrence of favourable soil patches at greater soil depths.

**Move in burrow.** During daylight periods individuals stay within their burrows to avoid high predation risk. While in their burrow, individuals optimise their position according to non-linear trade-offs between food quality, soil temperature and water potential conditions. In EEEworm the favourability of different soil and burrow patches are represented by an index of patch quality (Fig. S7 of the Supporting Information). Individuals sense patch quality within their burrow and preferentially move towards vertical patches with a higher index of patch quality. If a neighbouring soil patch is more favourable than an individual's existing burrow patch, it will extend its burrow to include this patch if the associated energy requirements of burrowing can be met. Individuals may ingest soil if energy requirements cannot be met during daylight hours, or if there is insufficient availability of litter (e.g. (Marhan & Scheu 2005)).

**Mate at surface.** Adult *L. terrestris* are hermaphroditic earthworms which require copulation with other adults every 3 months to transfer sperm and produce cocoons (Butt & Nuutinen 1998). In EEEworm, when an individual requires a mate it will sense the presence of another adult within a 20 cm radius of itself at the soil surface during dark hours. If another adult is available within this area, the individual will move towards the other adult until they mate. Adults can then produce cocoons for 3 months after copulation, before needing to mate again.

**Forage at surface.** Individuals forage on plant litter at the soil surface, typically within a 50 cm radius of the burrow mouth (Nuutinen & Butt 2005). If food is limited, individuals can

forage to greater distances from their burrows and return to a closer unoccupied burrow if available at day light.

## MODEL VALIDATION

Model validation is crucial in testing whether a model can predict individual and population-level dynamics in a range of environmental and management conditions. During model validation EEWorm simulates the conditions of published individual- and population-level experiments, and model outputs are compared to the independent published data. Full experimental details for model simulations are presented in Appendix S1 of the Supporting Information, and a summary of each is provided in the following sections.

**Individual-level experiments.** We simulated five different experiments which observed the effects of food quantity and quality, intraspecific competition, soil temperature and moisture on *L. terrestris* growth and reproduction, summarised in Table 2.

**Vertical distribution of *L. terrestris* populations in pasture.** Gerard (1967) reported the proportion of an *L. terrestris* population found at different soil depths throughout the year at Rothamsted, UK. Seasonal soil temperature and soil water potential are summarised in Fig. 1.

**Population responses to tillage practices.** Pelosi *et al.* (2008) recorded total, adult and juvenile population densities under fields formerly surface tilled (to 10 cm) or deep ploughed (to 30 cm) during two study years in France. Plots were cultivated with spring barley in 2006 and winter barley in 2007. The different tillage practices were modelled according to the study: surface tillage to a soil depth of 10 cm and deep ploughing to a soil depth of 30 cm, both annually on 1<sup>st</sup> October before the start of the field trial. EEWorm populations were sampled on the sample dates and to a soil depth of 30 cm as in the field sampling. Edwards and Lofty (1982) recorded total *L. terrestris* population density with annually direct drilled (5 cm), chisel ploughed (12.5 cm) or deep ploughed (20 cm) practices over a five year period in England. Soil temperature and water content measurements were extracted from the electronic Rothamsted Archive (e-RA) (Fig. 3a: light blue and green symbols represent

experimental period). Direct drilling, chisel ploughing and deep ploughing practices, to 5, 12.5 and 20 cm soil depths respectively, were simulated once a year on 1<sup>st</sup> October.

EEEworm populations were sampled on 15<sup>th</sup> September or May to a soil depth of 20 cm as in the field sampling.

(Table 2 here)

### **Modelling tillage effects**

*Direct mortality.* Here, we take a direct earthworm mortality rate of 50% during tillage, as was used for endogeic earthworms (Johnston *et al.* 2015). There is little evidence to support a higher or lower direct mortality rate for anecic earthworms. For instance, Crittenden *et al.* (2014) found earthworm populations to decline by 70% five days after moldboard ploughing in conventional arable fields. Longer-term data suggests higher mortality rates but this is presumably a combination of direct and indirect effects on soil conditions (e.g. (Wyss & Glasstetter 1992). In EEEworm, the 50% mortality rate is applied to the population present in the tilled soil layers, which depends on tillage practice.

*Litter removal.* The amount of plant litter at the soil surface is reduced following tillage events, and retained litter is redistributed within the tilled soil layers. The amount of plant residue that is retained varies between the surface tilled/direct drilled and chisel/deep ploughed scenarios. Yang and Wander (1999) reported litter retention of 78 % and 0.08 % in disk tilled and moldboard ploughed fields respectively, compared to no-till control plots. These values were used to model reductions in the quantity of litter available following tillage events, presented in Fig. S9 of the Supporting Information.

*Burrow destruction.* Burrow structures are destroyed by converting 100 % of the burrow patches in the tilled/ploughed soil layers to soil patches.

### **Model evaluation**

Data used to build and parameterise IBMs should be independent of the data used for model validation. As a simple measure of EEEworm's 'goodness of fit' to independent data we use coefficient of determination ( $R^2$ ) values, calculated as:  $1 - ((\text{residual sum of squares})/(\text{total sum of squares}))$ , with values closer to 1 representing better agreement between observed and predicted values. Note that if the model does not follow the trend of the data (e.g. the residual sum of squares from the model is higher than the total sum of squares from the data) the value of  $R^2$  can be negative. As in Johnston *et al.* (2015), our model parameter values are not estimated from the data and so conventional statistical methods of assessing  $R^2$  values (using  $p$  values) are not applicable. Values of  $R^2 > 0.5$  are taken to indicate good prediction of the independent data.

### **MODEL APPLICATION**

EEEworm was applied to simulate the long-term (116 year) effects of tillage practices on *L. terrestris* populations under historical and projected weather conditions for Rothamsted, UK. The tillage practices simulated were direct drilling and chisel and deep ploughing to 5, 12.5 and 20 cm respectively, as described in Edwards and Lofty (1982). Sixty six years of historical weather data (1950-2016: Fig. 3a) was extracted from the electronic Rothamsted archive (e-RA), with the initial five year period (1950-1955) used to stabilise the model population. Future 'baseline' weather projections for the next 50 years (2017-2067) were constructed as an extrapolation of observed increases and variations in soil temperature and water potentials over the previous 50 years (1966-2016) (Fig. 3b).

(Figure 3 here)

## RESULTS

### MODEL VALIDATION

**Individual growth and reproduction.** The EEEmorm model was able to capture the overall patterns in individual growth and reproduction recorded in the published experiments simulated (Fig. 4), with an average  $R^2$  value of 0.87. Four studies measured changes in individual biomass (Figs 4a – d) and two studies cocoon production (Figs 4e & f) over time, maintained at different densities, food quantities, diets, and soil moistures and temperatures. Increases in life cycle processes when individuals experience less competition for food resources (Fig. 4a) or were provided higher energy content foods (Figs 4a, d & f) are predicted well by the energy budget model as more energy is available for expenditure to growth and reproduction. General patterns of increased biomass at higher soil moistures and lower temperatures are also captured by EEEmorm, and mortality at higher temperatures in starvation conditions is also predicted well (Figs 4b & c). All model predictions except one (Fig. 4d: birch leaf diet) can be classified as ‘good’ according to the goodness of fit test ( $R^2 > 0.5$ ). While EEEmorm underestimated the difference between manure and birch leaves in Fig. 4d, it did capture the overall temporal pattern of the two diets.

(Figure 4 here)

**Vertical distribution of *L. terrestris* populations in pasture.** EEEmorm predictions of the vertical distribution of *L. terrestris* populations agree well with recorded data from Gerard (1967) (Fig. 5,  $R^2 = 0.68$ ), capturing important drivers of individual movement to deeper soil depths, such as migration to deeper soil layers during dry soil conditions in September.

(Figure 5 here)

**Population responses to tillage and ploughing practices.** EEWorm predictions of *L.*

*terrestris* population densities in response to tillage and ploughing practices are reported in Fig. 6 for the field trial presented by Pelosi *et al.* (2008) and Fig. 7 for the field trial by Edwards and Lofty (1982). Pelosi *et al.* (2008)'s field experiment recorded earthworm populations after the cessation of annual surface tillage and deep ploughing practices one year before the different field trials (i.e. 2006 and 2007 represent different plots, with tillage practices stopped in 2005 or 2006 respectively). Initial population densities, population structure and seasonal fluctuations in population density according to prevailing environmental conditions in the top 30 cm of the soil profile sampled are captured by EEWorm ( $R^2 = 0.82$ ).

(Figure 6 here)

Edwards and Lofty (1982)'s study demonstrates an increasingly detrimental effect of tillage intensity on *L. terrestris* populations in the top 20 cm of the soil profile sampled, which EEWorm captures well ( $R^2 = 0.90$ ) (Fig. 7). Average tillage effects (ploughed divided by direct drilled population density) are 0.44 and 0.56 for chisel ploughing in the data and EEWorm, respectively, and 0.16 and 0.28 for deep ploughing in the data and EEWorm, respectively. Differences between *L. terrestris* population densities sampled by Edwards and Lofty (1982) and Pelosi *et al.* (2008) are also captured by EEWorm due to variations in soil and environmental conditions, tillage frequency and the soil depth sampled.

(Figure 7 here)

**Tillage effects.** Comparisons between EEWorm predictions of tillage effects on *L. terrestris* populations (ploughed divided by direct drilled population density) and data from Edwards and Lofty (1982) when all tillage effects are included (as in Fig. 7) or when direct mortality, litter removal and burrow destruction effects are removed, are presented in Fig. 8. There is a

reduced goodness of fit between the model and data when any tillage effect is removed.

EEWorm predictions are particularly sensitive to litter removal ( $R^2 = -0.73$ ), followed by burrow destruction ( $R^2 = 0.28$ ) and direct mortality ( $R^2 = 0.61$ ), compared to model predictions when all tillage effects are included ( $R^2 = 0.86$ ).

(Figure 8 here)

## MODEL APPLICATION

EEWorm forecasts of ploughing effects on *L. terrestris* populations in arable fields over 111 years are presented in Fig. 9. Results follow the common trend of increasing ploughing effect (decreasing population density) with increasing tillage intensity reported in Edwards and Lofty (1982). In the chisel ploughed scenario, *L. terrestris* populations decline to below 50 % of the direct drilled population density post-2015, whilst the deep ploughed population declines to below 20 % of the direct drilled population post-2013. In contrast, the direct drilled population (which experiences only small tillage-induced effects on direct earthworm mortality) increases over time, with (albeit very weak) positive correlation between population density and soil temperature and water potential. Populations in the chisel ploughed scenarios tend to stabilise at a lower density post-2015 and only show a moderate negative relationship with soil temperature and water potential, whilst deep-ploughed populations continue to decline and show a stronger negative relationship with soil temperature and water potential (Figs 9b & c).

(Figure 9 here)

## DISCUSSION

The mechanistic EEWorm model indicates that tillage effects on important soil ecosystem engineers (*Lumbricus terrestris*) are driven by the removal of plant litter from the soil surface, while interactions between litter removal, mortality and burrow destruction are key in

predicting population responses to different tillage intensities (Fig. 8a). Under soil warming, higher soil temperatures and reduced soil water potentials in our weather scenario place additional energetic demands on individual earthworms (Figs 4b & c), and when demands cannot be met with sufficient food resources population declines are exacerbated (Fig. 9). In EEEworm, greater population declines in deep ploughed scenarios are due to greater plant litter depletion, which intensifies temperature and soil water stress on populations (Figs 9b & c). Yet, simulations also showed that deep and chisel ploughed populations avoid total collapse under continued disturbance through *L. terrestris* adaptive behaviour: individuals burrow to deeper soil depths to avoid increasingly dry conditions in the tilled soil layers. In contrast to the ploughed scenarios, *L. terrestris* populations responded positively to soil warming under direct drilling, where sufficient food was available to meet the energy costs associated with higher metabolic rates. The importance of *L. terrestris* as an ecosystem engineer suggests that their higher population abundances in direct drilled fields provide a suite of soil functions essential for improving plant growth (Spurgeon *et al.* 2013; van Groenigen *et al.* 2014).

In line with our predictions, Simonsen *et al.* (2010) reported decreasing adult *L. terrestris* population densities from 28/m<sup>2</sup> in no-till to 3/m<sup>2</sup> in chisel ploughed fields in Wisconsin, whilst Stroud *et al.* (2016) observed densities < 1/m<sup>2</sup> in long-term conventionally managed plots at Rothamsted.

Here, we predict average *L. terrestris* population densities of 29, 13 and 4/m<sup>2</sup> in direct drilled, chisel and deep ploughed scenarios after 51 simulation years under historical weather conditions at Rothamsted. Our finding that tillage effects are strongly influenced by litter layer removal is further supported by observed positive correlations between organic amendment quantity and *L. terrestris* abundance in arable fields (Sizmur *et al.* 2017). Vice versa, the positive effects of no-till systems on anecic earthworms are due to improved food availability alongside a lack of physical disturbance. In a global meta-analysis, Briones and Schmidt (2017) found that no-till systems (compared to conventional controls) had a

particularly positive effect on *L. terrestris* abundance which increased by 178% compared to an overall earthworm abundance increase of 137%. These results indicate the importance of litter retention for optimal management of ecosystem functions facilitated by this important ecosystem engineer.

Long-term responses of earthworms to soil warming have not been well studied. However, a study in temperate grassland showed soil warming to significantly increase anecic earthworm numbers, while endogeic and epigeic populations declined (Briones *et al.* 2009). This response was likely due to the ability of anecic earthworms to burrow to much deeper soil layers than other functional groups of earthworm, aiding better adaptation to adverse soil surface conditions. Whether earthworms acclimatise to soil warming is unknown, and adaptive strategies towards temperature shifts likely depend on species-specific behaviours (Chuang, Lee & Chen 2004). The direction and magnitude of warming effects on earthworm abundance will also be strongly influenced by soil water conditions (Eisenhauer *et al.* 2014) and plant litter availability and quality (Daniel 1991). Yet, while we know that earthworms exhibit preferences for specific environmental conditions, and here EEEworm predictions of individual weight gain and loss at different soil moistures and temperatures agree well with published data (Figs 4b & c), more knowledge is needed on how extreme events affect individual life cycles. For instance, very little is known about the effects of flood and drought conditions on earthworm physiology and behaviour and the resultant effects that this may have on soil health. In the same way, plant production and quality will likely be altered under environmental change, shifting the relationships between earthworms, soil functions and plant productivity (Wardle *et al.* 2004). Understanding how soil organisms are affected by various scenarios of environmental change, ideally through coupled empirical and modelling studies, would allow better prediction of soil populations in both managed and unmanaged ecosystems.

Whether anecic earthworms can replace the soil functions provided by tillage will depend on a number of site-specific factors, and predictive tools need further development to identify best practices for sustainable soil management at the field scale. A clear aim for modelling approaches like EEEworm is to link individual earthworm activities and population dynamics to ecosystem functions. This would require: 1) linking individual activities (movement, burrowing, casting, foraging) to changes in soil structure and properties (e.g. aggregation, bulk density, water infiltration rates); 2) linking biogenetic structures (e.g. burrows, casts) to soil microbial populations; 3) representation of the nutritional ecology of earthworms within the soil system and feedback to nutrient and carbon cycles; 4) interactions with other soil organisms and functional groups within soil food webs; and 5) interactions with plant components (e.g. roots) and feedbacks between plant life cycles. Empirical studies quantifying the specific relationships between soil biota activities and soil functions are needed to support these developments.

Mechanistic models are needed to find pathways to sustainable land management, by identifying how land management and climate change affect ecosystem functioning. *L. terrestris* is a keystone species closely associated with essential soil functions and ecosystem services such as primary productivity, soil fertility and flood prevention.

Experimental evidence (e.g. Stroud *et al.* 2016) and our simulations suggest *L. terrestris* populations are decimated by deep ploughing mainly due to removal of the litter layer following tillage. In the context of soil warming through climate change, removal of the litter layer will exacerbate *L. terrestris* population declines in ploughed fields if soil conditions also become drier as in our simulation. Our results suggest that pre-emptive strategies to mitigate climate change impacts on soil health in agroecosystems should focus on decreasing tillage intensity and retaining crop residues and organic amendments at the soil surface. As *L. terrestris* vulnerability varies seasonally, recommendations for conserving *L. terrestris* populations will depend on site-specific combinations of environmental conditions and

management practices. Tools like EEWorm are needed to better inform sustainable land management strategies.

### Authors' contributions

AJ, RS and PT conceived the ideas and designed methodology; AJ and PT developed the conceptual model; AJ collected literature data, wrote the model code, and conducted and analysed model simulations; AJ and RS led the writing of the manuscript. All authors contributed critically to the drafts and gave final approval for publication.

### Acknowledgements

We thank Dr Celine Pelosi for sharing of field data, and the Lawes Agricultural Trust and Rothamsted Research for data from the e-RA database. The Rothamsted Long-term Experiments National Capability (LTE-NCG) is supported by the UK Biotechnology and Biological Sciences Research Council and the Lawes Agricultural Trust. This research has been financially supported by a NERC Soil Security Programme fellowship (NE/N019504/1).

### Supporting Information

Additional Supporting Information may be found in the online version of this article:

**Appendix S1.** Additional details of EEWorm model parameters, variables and simulations.

**Table 1.** Default parameter values of the *Lumbricus terrestris* EEEworm model with sources.

Symbol	Definition	Value	Unit	Reference	Notes
$A_e$	Assimilation efficiency	0.55	---	Daniel (1991)	p. 207
$B_0$	Taxon-specific normalization constant	360	---	Ehnes, Rall and Brose (2011)	Data given as Supporting Information.
$E$	Activation energy	0.32	eV		
$E_c$	Energy content of tissue	7	kJ/g	Peters (1983)	p. 235
$E_s$	Energy cost of synthesis	3.6	kJ/g	Sibly and Calow (1986)	p. 54-55
$E_x$	Energy content of food	0.56 – 21.2	kJ/g	Range depends on diet: see text.	
$IG_{max}$	Maximum ingestion rate	0.37	g/hour/g <sup>2/3</sup>	Curry and Bolger (1984)	Fig. 3, p. 255.
$B_c$	Energy cost of burrowing	0.0103	kJ/cm/hour	Quillin (2000)	Fig. 6b and Table 1
$M_b$	Mass at birth	0.053	g	Butt (1993)	Fig. 1, p. 136
$M_c$	Mass of cocoon	0.061	g	Butt (1993)	Table 1, p. 137
$M_p$	Mass at sexual maturity	4.2	g	Butt, Frederickson and Morris (1992)	Fig. 4, p. 132 5
$M_m$	Maximum asymptotic mass	8.5	g	Butt (1993)	Fig. 1, p. 136.
$r_B$	Growth constant	0.0023	/hour	Butt (1993)	Fig. 1, p. 136.
$r_m$	Maximum rate of energy allocation to reproduction	$2.10 \times 10^{-4}$	kJ/g/hour	Butt, Frederickson and Morris (1992)	Fig. 1, p. 1322.
$T_0$	Incubation period	90	days	Butt, Frederickson and Morris (1992)	Fig. 3, p. 1323
$T_{ref}$	Reference temperature	288.15	kelvin	Butt, Frederickson and Morris (1992)	p. 1325
$\mu$	Background mortality rate	0.18	%/day	(Daniel 1990)	Table 5 (p. 31) and Table 6 (p. 32) for 10-17.5 °C

**Table 2.** Experimental conditions from published laboratory studies replicated by EEEworm to validate the models ability to predict *L. terrestris* life cycle processes with independent data. *N* is number of individuals per experiment, SCS is separated cattle solids and  $E_x$  is the energy content of food.

Study	N	Initial mass (g)	Food source	Food/soil quantity (g)	Ex (kJ/g)	Temp (°C)	Soil Moisture (%)
Lowe and Butt (2002)	(1 ) + 2	(5) 0.055	Milled and unmilled SCS	60/900	0.90 -1.15	15	25
Berry and Jordan (2001)	1	0.07	Horse manure	10/750	1.02	10-30	20-30
Daniel, Kohli and Bieri (1996)	1	0.875	None	0/450	0	10-25	40
Butt (1993)	4	3.3	SCS	500/1500	2.05	20	25-30
Butt (2011)	1	6.53	Horse manure	100/600	1.19	15	25
Butt (2011)	1	7.32	Birch leaves	100/600	1.19-1.20	15	25
