## EARLY ONLINE RELEASE

This is a preliminary PDF of the author-produced manuscript that has been peer-reviewed and accepted for publication. Since it is being posted so soon after acceptance, it has not yet been copyedited, formatted, or processed by AMS Publications. This preliminary version of the manuscript may be downloaded, distributed, and cited, but please be aware that there will be visual differences and possibly some content differences between this version and the final published version.

The DOI for this manuscript is doi: 10.1175/JCLI-D-17-0871.1

The final published version of this manuscript will replace the preliminary version at the above DOI once it is available.

If you would like to cite this EOR in a separate work, please use the following full citation:

#### Abstract

19 In Part 1 of this study, the annual cycle of the Northern Hemisphere storm-tracks was investigated 20 using feature tracking and Eulerian variance based diagnostics applied on both vorticity and 21 meridional wind. Results were presented and discussed for the four seasons at both upper (250hPa) 22 and lower (850hPa) tropospheric levels. Here, using the meridional wind diagnostics, the annual 23 cycles of the North Pacific and North Atlantic storm-tracks are examined in detail. This is done using 24 monthly and 20° longitudinal sector averages. Many sectors have been considered, but the focus is 25 on sectors equally spaced in the two main oceanic storm-tracks situated at their western, central 26 and eastern regions, the western ones being mainly over the upstream continents. 27 The annual cycles of the upper and lower tropospheric storm-tracks in the central and eastern 28 Pacific, and western and central Atlantic sectors all have rather similar structures. In amplitude, each 29 sector at both levels has a summer minimum and a relatively uniform strength from October to 30 April, despite the strong winter maxima in the westerly jets. However, high intensity storms occur 31 over a much wider latitudinal band in winter. The storm-track in each sector moves poleward from 32 May to August and returns equatorward from October to December, and there is a marked

asymmetry between spring and autumn.

34 There are many differences between the North Pacific and North Atlantic storm-tracks, and some 35 of these seem to have their origin in the behaviour over the upstream East Asian and North 36 American continents, suggesting the importance of seeding from these regions. The East Asian 37 storm-track near 48°N has marked spring and autumn maxima and weak amplitude in winter and 38 summer. The 33<sup>o</sup>N track is strong only in the first half of the year. In contrast, the eastern North American storm-track is well-organised all year, around the baroclinicity that moves latitudinally 39 with the seasons. The signatures associated with these features are found to gradually decrease 40 downstream in each case. In particular, there is very little latitudinal movement in the storm-track in 41 42 the Eastern Atlantic.

43 **1** Introduction

The winter Northern Hemisphere (NH) storm-tracks have been the subject of many 44 previous studies (e.g. Blackmon, 1976; Chang et al, 2002; Hoskins and Valdes, 1999; Hoskins 45 and Hodges, 2002), In his seminal study, Nakamura (1992) presented pictures of the annual 46 cycle of the North Pacific and North Atlantic storm-tracks based on high pass filtered 47 variance of geopotential at 250hPa and the sea-level pressure. His focus was on the winter 48 half of the year and he contrasted the mid-winter minimum in the Pacific with the expected 49 winter maximum in the Atlantic. Subsequent papers, e.g. Ren et al. (2010), Penny et al., 50 (2010), Chang and Guo (2012), Ren et al (2014), and recently Afargan and Kaspi (2017) (and 51 also, very recently, Schemm and Schneider, (2018)) have shown annual cycles but have 52 53 focussed on this winter behaviour. However, relatively little attention has been given to the 54 NH storm tracks in other seasons or to the details of their annual cycle.

55 An earlier study whose results might be expected to be relevant to the storm-tracks is 56 that of Fleming et al (1987) who considered the annual cycle of the zonally averaged 57 westerly wind at 500hPa. The focus of Fleming et al (1987) was the asymmetry between 58 spring and autumn, with the latitudes of the jet in spring and autumn being 33°N and 46°N, 59 respectively. The largest amplitudes and southern-most latitudes were found to occur in 60 mid-winter, and weakest amplitudes in July and highest latitudes in August.

This paper forms the second part of a study of the annual cycle of the observed NH storm-tracks. In Part 1 of this study (Hoskins and Hodges, 2017, hereafter HH1) high-pass standard deviation and cyclone tracking metrics were applied to vorticity and meridional wind in the upper troposphere (250hPa) and lower troposphere (850hPa) to produce the seasonal average storm tracks which were presented and discussed. Comparisons between

66 the results for different metrics, variables, and levels, and between the Pacific and Atlantic storm-tracks were made. Amongst the results it was found that the North Pacific upper 67 tropospheric storm-track is indeed weaker in winter than in autumn or spring when viewed 68 using high-pass standard deviation of both variables, but with tracking measures and in the 69 70 lower troposphere this minimum was less marked. The seasonal positions of the storm-71 tracks were in general found to be qualitatively consistent with that of the zonally averaged 72 jet found by Fleming et al (1987). However, these and other aspects would benefit from a 73 more detailed view of the annual cycle. This is the motivation for this second paper in which the annual cycle of the two major Northern Hemisphere storm-tracks, the North Pacific and 74 75 the North Atlantic storm-tracks are examined in detail using averages over particular, representative longitudinal sectors and for the calendar months. The primary motivation for 76 this paper and its companion is to further the basic understanding of storm-tracks and the 77 78 ability to diagnose the storm-tracks in climate models. It is not directly aimed at the impacts 79 associated with storms, though this is off course an important area for study.

80 Sector averages have been used by a number of authors in order to summarise the storm-track behaviour in broad regions. For example, Nakamura (1992) used 60° sectors in 81 82 the Pacific and the Atlantic, and Penny et al (2010), and Afargan and Kaspi (2017) used 40° 83 sectors. These sector widths were satisfactory for the topics considered, but it is clear from the geographical storm-track pictures shown in HH1 that the storm-tracks in some regions 84 85 can vary significantly over such longitudinal ranges. In particular averages over a broad 86 range of longitudes are problematic for a south-west to north-east tilted storm-track like the North Atlantic in winter. Here we will use narrower 20° sectors in order to obtain a more 87 88 local picture of the storm-track behaviour. The 37 years of reanalysis data used here is

sufficient that results for such narrow sectors based on diagnostics of meridional windgenerally show coherent behaviour from month to month in the annual cycle.

91 Previous studies showing the annual cycle, e.g. Nakamura (1992), Nakamura and Sampe (2002), Ren et al. (2010), Chang and Guo (2012) and Afargan and Kaspi (2017), have mostly 92 used a high pass variance measure for the storm-track. However, Penny et al (2010) 93 94 showed the results from both variance and feature tracking, but focussed on the tracking results. (Very recently, Schemm and Schneider, 2018, have tracked surface cyclones and 95 96 used variance measures in the free atmosphere.) Here both storm-track metrics will be 97 given equal weight in the discussion. Following Nakamura (1992), the high pass variance technique has mostly been applied to geopotential at an upper tropospheric level, but Ren 98 99 et al. (2010) applied it to meridional wind at an upper tropospheric level. Nakamura (1992) 100 also presented the annual cycle for the variance of mean sea level pressure but there has been limited discussion of lower tropospheric metrics. In this paper equal weight will be 101 102 given to high-pass variance and feature tracking measures. The same metrics applied to an 103 upper tropospheric level, 250hPa, and a lower tropospheric level, 850hPa, will be discussed for each sector. The main results presented here will be for meridional wind, V. Those 104 obtained using vorticity are generally found to be similar. 105

The paper continues in Section 2 with a brief discussion of the data and methodologies used. Section 3 presents the results in separate sub-sections for the North Pacific, North Atlantic and Mediterranean, and Section 4 gives some concluding comments.

109

#### 110 2 Data and methodology

The data and basic methodology are the same as in HH1, where full details are given. The basic data source is the European Centre for Medium-Range Weather Forecasts (ECMWF) Interim reanalysis (ERAI) (Dee et al, 2011) for the years 1979 to 2016. The data used in this study is the 4 times per day meridional wind, V, on the 850 and 250hPa levels.

115 Two approaches to diagnosing the storm-tracks are employed. The first is based on the 2-116 6 day band-pass filtered variances (Blackmon, 1976), presented in terms of the Standard 117 Deviation (SD). The second approach uses objective feature tracking as in the NH winter 118 study of Hoskins and Hodges (2002), and is the same as used in HH1, where more details can be found. As in HH1, the diagnostics are performed at 250hPa, representing the upper 119 120 troposphere, and 850hPa, representing the lower troposphere. In HH1 the tracking results were presented for extrema in two fields, vorticity and the modulus of meridional wind, 121 122 |V|. In HH1 a detailed discussion of using the latter and the relative advantages of the two 123 variables is given. The latter is equivalent to tracking both positive and negative extrema in V and combining the results. Briefly, the justification for using |V| is that the growth of 124 125 storms depends on both warm air moving polewards and cold air moving equatorwards, and in addition tracking |V| provides the best comparison with the band-pass SD of V, which 126 127 also makes no discrimination between signs. In this paper, SD of V and tracking of |V| will be used instead of vorticity as the finer scales described by vorticity sometimes lead to some 128 lack of continuity between months in sectors as narrow as the ones used here. Tracking has 129 also been performed separately for positive and negative V extrema and these results will 130 be mentioned in cases where this detailed additional information is of interest. 131

The sectors in which the storm-tracks are to be studied in detail are shown in Figure 1. 132 This shows the December-February (DJF) winter-time cyclone track density and mean 133 134 intensity for maxima in the modulus of the meridional wind at 850hPa ( $V_{850}$ ), similar to 135 Figure 10a of HH1. As discussed in detail there, the North Pacific and North Atlantic stormtracks are clearly delineated at this level. The sectors have been chosen to sample the 136 western/upstream, central and eastern/downstream regions of the two main storm-tracks. 137 138 They are all 20° in longitude, with three equally spaced (with 30° separation) in the Pacific 139 storm-track and three equally spaced (with 10° separation) in the Atlantic storm-track. The sectors are: West Pacific (WP: 110E-130E), Central Pacific (CP: 160E-180E), East Pacific (EP: 140 141 150W-130W), West Atlantic (WA: 80W-60W), Central Atlantic (CA: 50W-30W), East Atlantic (EA: 20W-0W). The nomenclature, West, Central and East are with reference to the relevant 142 storm-track and not the ocean basin. For example, in the latitudes of interest, the WP sector 143 144 is mainly in East Asia, and WA is more in North America than over the Atlantic. To 145 understand the context further upstream and the continuity between sectors, results from a number of other sectors have been computed and considered. Sectors further west over 146 147 Asia (100°E-120°E) and over North America (90°W-70°W) are shown in the Supplementary Material. Also shown there are the results for a 10°E-30°E sector that gives a picture of the 148 seasonal cycle of the Mediterranean storm-track. In addition it shows the extension of the 149 150 North Atlantic storm-track into Europe, though the interruption of the 850hPa surface by 151 the Alps should be noted as giving a region of doubtful validity of the diagnostics between the two storm-track regions. The borders of the three sectors shown in the Supplementary 152 Material are indicated by yellow lines in Figure 1. 153

In the following Section, the North Pacific storm-track will be discussed first, starting with
 the CP sector, motivated by the previous interest in the mid-winter minimum in the Pacific.

156 **3 Results** 

157 **3.1** The North Pacific

#### 158 **3.1.1 The Central Pacific (CP)**

The CP sector zonal mean of SD of the band-pass V at both 250hPa and 850hPa are 159 shown as functions of time of year (abscissa) and latitude (ordinate) in Figures 2a, c. The 160 January to December period is continued by a repetition of the 6 months of January to June, 161 162 so that the annual cycle is clear throughout the year. Overlain on the SD panels are contours 163 of a relevant zonal wind, U. At 250 hPa, U is shown on the dynamical tropopause (the PV=2 surface, see e.g. Hoskins (2015)) and highlights both the sub-tropical and polar jets. This is 164 used because of its theoretical importance for developments in the upper troposphere in 165 general (see e.g. Hoskins and James, 2014). However, U on the 250hPa level (not shown) 166 167 itself is very similar, showing jets at the same latitudes with only slightly smaller strengths. 168 At 850 hPa, the zonal wind at that level is used. Figures 2b, d give the track density (line contours) and mean intensity (filled colour contours) for |V| maxima at the same upper and 169 lower tropospheric levels. 170

171 In the CP, the SD at both levels (Figures 2a, c) is dominated by the middle latitude storm-172 track, and shows its annual cycle in amplitude and latitude. The mid-winter minimum is 173 apparent in both the upper and lower troposphere, though much less so at the lower 174 (850hPa) level. This contrasts with the winter maximum in U at both levels. A marked mid-175 summer minimum in SD, as well as in U, is apparent at both levels. It is also clear that the 176 autumn maxima are further poleward than those in spring.

The tracking panels (Figures 2b, d) give a more complex picture. In the upper troposphere, the track density (Figure 2b) shows spring and autumn maxima. The mean intensity is large in the autumn storm-track, but in mid-winter the higher intensity values

are less confined to the region of high track density, with the highest values found at even lower latitudes than the track density maximum. In spring, the maximum intensities are back in the storm-track, but there is now a secondary maximum at low latitudes. The midwinter minimum in SD is therefore a reflection of both fewer storms and reduced intensities in the main storm-track region. However there are strong storms with tracks over a wide range of latitudes.

The tracking picture is again simpler in the lower troposphere (Figure 2d) with the highest intensities in the storm-track region throughout the year. Here, the overall impression is of a single extended maximum from September to May. The weak mid-winter minimum in SD is related to slightly weaker mean intensities in the storm-track region. However, at that time the region of high intensities also spreads in latitude, this time particularly on the poleward side.

The almost straight bounding contours on the poleward side of the 850 hPa track density for the main storm-track imply that it stays equatorward of the Kamchatka Peninsula all year. At both levels there is also a polar, Arctic maximum in track density in the summer time (Serreze and Barrett, 2008). At 850hPa, this leads to a weak maximum in SD (Figure 2b) there, but the more prominent Arctic maximum in SD is in winter, associated with the larger intensities at that time of year (Zhang et al., 2004)

At both levels and in both measures, the major storm-track movement in latitude largely reflects that of the zonal wind, with the upper tropospheric storm-track slightly poleward of the maximum in the westerlies. However, in the upper troposphere in winter the relationship is less definite. The SD maximum does not move as far equatorward as that in

U. The track density maximum is north of the jet but the storms with highest mean intensityare slightly south of the jet.

204 To study in more detail the annual cycle in the main storm-track, the latitude (ordinate) of the SD maximum and the amplitude (abscissa) of the maximum in each month are shown 205 206 in Figures 3a and c, respectively for the two levels. The months are shown as dots with 207 different colours and the annual cycle is made clearer by lines joining successive months, starting at January and finishing at December. In the upper troposphere (Figure 3a), the 208 209 mid-winter minimum is apparent in that the March, April and May, and October and 210 November amplitudes are all slightly higher than those in January and February when the storm-track is at relatively low latitudes. 211

The annual cycle shows a poleward shift and growth from February to March, a sharp 212 decrease in amplitude from May to June, a poleward shift through July to August, a shift 213 equatorward by September and growth that continues into November followed by a further 214 215 equatorward shift and reduction in amplitude through December to January. Figure 3c 216 shows that at 850hPa the mid-winter shift equatorward to below 40°N does not occur and the mid-winter minimum is less marked, with the amplitude being similar over the extended 217 winter from October to April. As in the upper troposphere, minimum values again occur 218 219 from June to August and this is the period of the main poleward shift. The main increase in 220 amplitude occurs from then until October and the main decrease in latitude from November 221 to December. The hysteresis-like curves at both levels clearly illustrate the asymmetry 222 between spring and autumn.

223 It is of interest to obtain similar annual cycle summaries for the main storm-track using 224 the tracking of |V|. In each month the track density shows a relatively sharp maximum, but

the mean intensities have a broader distribution. Therefore it has been decided to identify 225 the latitude of the storm-track by the track density maximum, and use the mean intensity at 226 that latitude as the measure of strength, with these two acting as the descriptors of the 227 storm-track behaviour for each month. This gives the annual cycle summary pictures in 228 Figures 3b and d for the two levels. The behaviour at both levels is generally similar to that 229 shown for the SD in Figures 3a and c. Again apparent are: the January-February 230 231 equatorward displacement with a minimum in amplitude at both levels, low intensities and 232 a poleward shift in the period June-August, and a latitude difference between spring and autumn, with the spring latitude closer to that of winter and the autumn storm-track 233 234 latitude closer to that of late summer. With this diagnostic, the mid-winter minimum is apparent at 850hPa as well as 250hPa. 235

It is of interest to not that in this sector, the large sea surface temperature gradients associated with the extension of the Kuroshio are in the latitude band 30°N-40°N, and only the winter storm-track can be affected directly by them.

#### 239 **3.1.2 West Pacific (WP)**

The WP sector has its own intrinsic interest. In addition there has been much discussion (e.g. Hakim, 2003; Orlanski, 2005; Chang, 2005; Robinson, 2006; Penny et al., 2010; Chang and Guo, 2012) of the seeding from the WP of the storm-track in the CP, in particular in its possible importance in the mid-winter minimum there. The Kuroshio occurs only in the easternmost part of this 20° sector and then with a south-north orientation. The zonal averages in the WP sector are not designed to diagnose the impact of the Kuroshio and in any case the scale resolved by the data used is probably not suitable for this.

Figure 4 shows the WP sector average SD and tracking results at the two levels. The SD 247 results (Figures 4a, c) for the main storm-track are generally weaker versions of those for 248 the CP (Figures 2a, c). However, in this sector the mid-winter minimum in the upper 249 troposphere is almost as marked as the mid-summer minimum. The upper tropospheric 250 251 tracking diagnostics (Figure 4b) are also similar to those for the CP (Figure 2b), except that the mean intensities are weaker and the mid-winter minimum is more evident in both track 252 253 densities and intensities. The behaviour is largely decoupled from that of the jet (Figure 4a) 254 except that there is an intensity maximum that is coincident with the winter jet maximum.

255 There are indications of a more complex structure in the lower tropospheric SD (Figure 4c). In Spring there are signs of separate maxima near 45<sup>o</sup>N and 30<sup>o</sup>N, and in Spring and 256 Autumn also maxima near 65<sup>o</sup>N. In the tracking results (Figure 4d) these features become 257 more apparent. In the latitudes 30°-50°N the track density exhibits a double structure in 258 latitude. The northern maximum, centred on 48<sup>0</sup>N, is present most of the year, and is 259 260 prominent from March to June and August to December. Its importance for the Pacific 261 storm-track has been discussed by Nakamura (1992), Hakim (2003), Orlanski (2005), Chang (2005), Penny et al. (2010), and Chang and Guo (2012). The southern maximum, centred on 262 263 33<sup>0</sup>N, is present only in the first half of the year, and is prominent from February to May. 264 Nakamura and Sampe (2002) mentioned the possible importance for the Pacific storm-track of waves on this southern branch, and Chang (2005) gave evidence of constructive 265 266 interference between wave packets on the two tracks.

Associated with the 850 hPa double track in spring and the single track in autumn, there are weak maxima in the westerly winds at the same level (Figure 4c). In the autumn the northern track is prominent at both levels in both track density and SD (Figure 4), so that the

270 systems are vertically deep. However, in the spring the upper tropospheric track is centred 271 between the two lower tropospheric tracks, so that a linkage with either is possible. This behaviour contrasts with that in the CP where the upper and lower tropospheric track 272 densities are coherent throughout the year. The two tracks in WP can be seen in the winter 273 274 and spring 850hPa tracking pictures given in HH1 for meridional wind (Figure 10a, b) and 275 positive vorticity (Figure 7a, b). For winter, the northern track is the south-eastward 276 extension of the Siberian track discussed by Wallace et al. (1988) and the southern one, in 277 the region of the sub-tropical jet, was highlighted by Chang and Yu (1999). Later in the year, the latter corresponds to the Spring Persistent Rains in China discussed by, for example, Tian 278 and Yasunari (1998). The possible importance of the WP behaviour for that in CP will be 279 discussed further in Section 4. 280

281 Also clearly marked in the 850hPa tracking results (Figure 4d) is a maximum in track density near 65<sup>o</sup>N from March to October with a weak minimum in mid-summer. The mean 282 283 intensities emphasise the spring and autumn periods, making this storm-track feature 284 consistent with the signatures near 65<sup>o</sup>N commented on above. Looking again at Figure 4b, similar features are also apparent in the 250hPa tracking results. The features are even 285 clearer in the 100E to 120E sector shown in Figure S1. Referring to Figures, 7, 8, 10 and 11 of 286 HH1, the presence of the 850hPa eastward extension near 65<sup>0</sup>N from the Siberian storm-287 track to 110E-120E is clear in both vorticity and meridional wind, and in both SD and 288 289 tracking. However, in the upper troposphere the track leading south-east towards the region of the 48<sup>0</sup>N lower troposphere track is dominant. 290

291 Near 15<sup>0</sup>-20<sup>0</sup>N, the May-November maximum in track density (Figures 4b, d) is more 292 marked at both levels than in the CP, and is the signature of westward moving Western

Pacific tropical cyclones. At 850hPa the track density maximum is accompanied by large
mean intensities and so the signature is seen also in the SD (Figure 4b).

295

#### **3.1.3 East Pacific (EP)**

297 Moving eastwards from the CP, the EP SD and tracking results at the two levels are 298 shown in Figure 5. The main storm-track in the upper troposphere (Figures 5a, b) again 299 exhibits a mid-winter minimum in SD and in track density. In mid-winter the spread of larger SD values to lower latitudes is associated with a secondary maximum in track density 300 accompanied by high intensities. This is the signature of the cut-off lows, the "subtropical 301 302 cyclones" whose surface features are referred to as Kona lows and that have been discussed 303 by, for example, Simpson (1952), and Otkin and Martin (2004). The high intensities at low latitudes seen in CP in the winter (Fig. 2b) may also reflect such features. 304

In the lower troposphere (Figure 5c, d) both the SD and track density give a slight 305 306 emphasis to the first half of winter. The mid-winter expansion to lower latitudes is again 307 apparent in the tracking fields (Figure 5d). At this lower level, the storm-track in this sector 308 is bounded near 58<sup>0</sup>N at all times of the year by the southern coast of the Alaskan 309 Peninsular. At low latitudes the track density signature of westward moving Eastern Pacific 310 tropical cyclones is seen from June to October. In high latitudes the track density again has a summer maximum in the Arctic, off the northern coast of Alaska, but it is the winter 311 intensity maximum that is picked up more strongly by the SD. 312

At both levels, the westerly winds themselves show a slight winter minimum in this sector. The storm-tracks and the winds tend to move together through the annual cycle,

315 with the storm-track slightly poleward of the maximum winds except for the upper 316 troposphere from January to April.

Figure 6 shows the EP annual cycle summaries for SD and tracking and for the two levels using the same format as for CP in Figure 3, and the results are quite similar to those. All four panels show a fairly flat maximum from October to April with the actual peak mostly in December. Each then shows a strong reduction in magnitudes to those of the summer, this being about 50% at the lower level. Each also show a lower latitude for the storm-track in winter and early spring, and a higher latitude in late summer and early autumn. This asymmetry between spring and autumn is again marked.

324

#### 325 3.2 The North Atlantic

326 **3.2.1 West Atlantic (WA)** 

As seen in Figure 1, the WA sector includes eastern North America. The Gulf Stream is present at the eastern portion of the sector, moving from near 30<sup>o</sup>N to near 40<sup>o</sup>N across the sector. As with the case of the WP, the zonal average in the sector will not, and is not intended to capture the details of the atmospheric interaction with the Gulf Stream.

The WA sector average annual cycle results are given in Figure 7. In the annual cycle, the track densities (Figures 7b, d) have a weak summer maximum but show less variation in amplitude through the year than in the CP and EP. The mean intensities are a maximum in the winter half of the year and lower in the summer. The latter is reflected in minima in the SD results (Figures 7a, c) in summer, but these minima are not as marked as in the Pacific. The upper tropospheric mean intensity (Figure 7b) again spreads to lower latitudes in winter, but with the low number of tracks this is only weakly reflected in SD (Figure 7a), and

is not as prominent as in the CP and EP. The signature of westward moving Atlantic tropicalcyclones is apparent in all the panels from June to October.

As in the CP, the upper tropospheric westerly winds are strongest in mid-winter (Figure 7a). However, unlike the Pacific, the jet continues to move slightly equatorward until March. In the upper troposphere in April-May a second westerly maximum appears some 15° further north, and it is the northern maximum that continues through the summer, moving slowly poleward. The storm-track in all measures is poleward of the strongest westerlies, with the displacement becoming large as the westerly jet continues to move equatorward after January.

Figure S2 in the Supplementary Material, shows results for the sector centred 10° further west. Results have also been obtained for a sector 10° further east (not shown). The stormtrack diagnostics are all very similar but with slightly reduced SD amplitude and track mean intensities to the west which increase to the east.

Summaries of the annual cycle in the latitude and strength of the middle latitude storm-351 352 track for the WA sector are given in Figure 8. At 250hPa (Figures 8a, b) the storm-track is furthest equatorward in February, near 40°N, and furthest poleward in August-September, 353 near 50°N, much as in the Pacific. The amplitude varies little in the period September to 354 355 May with a weak maximum in November. The minimum occurs in July and August, but the summer reduction is smaller than in the Pacific. A significant poleward shift does not occur 356 until May or June and the return to lower latitudes does not occur until October or 357 358 November. The 850hPa results (Figures 8c, d) are similar, showing loops from low latitudes and high amplitudes in the period November to April and high latitudes and low amplitudes 359 360 in July and August, with the early summer and autumn changes occurring first in amplitude.

In the lower troposphere the amplitude range is only slightly less than in the Pacific. In all the diagnostics, the latitude of the storm-track changes little from December to April, the period when the upper tropospheric jet is still moving slowly equatorward. As discussed in HH1, it is only in this period that the storm-track is close to the region of strong Gulf Stream SST gradients.

366

#### 367 3.2.2 Central Atlantic (CA)

The CA sector average annual cycle results are presented in Figure 9. There are again considerable similarities with the WA (Figure 7), though the amplitudes of the SD (Figures 9a, c) and the mean intensities (Figures 9b, d) are slightly larger at both levels, and the latitude ranges in the annual cycles are somewhat smaller. The summer minima in SD at the two levels are even less marked than in the WA. This is associated with a stronger summer maximum in track density at both levels.

The two levels also have secondary maxima in track density in winter. In the lower troposphere (Figure 9d) this is quite strong and the definite mid-winter maximum in SD is consistent with this. In the upper troposphere, the winter maxima in track density (Figure 9b) and in SD (Figure 9a) is weak and the main impression is of little change in SD strength from October to March.

In the upper troposphere the large intensities again extend to lower and higher latitudes, even slightly more than in the WA. The northern side of the 850hPa storm-track (Figure 9d) is bounded by Greenland throughout the year.

As in the other sectors it is only during the extended winter period that the storm-track is at sufficiently low latitude to be directly affected by the stronger sea surface temperature

gradients near 40°N in the extension of the Gulf Stream. Afargan and Kaspi (2017) have recently discussed the existence of a winter minimum in the Atlantic storm-track, particularly in strong jet years. The diagnostics presented here for sectors from 90°W to 30° W emphasise rather that the intensity of the storm track changes little over the extended winter season.

#### 389 3.2.3 East Atlantic (EA)

For the EA sector (which includes part of Western Europe), the 250hPa annual cycles in sector average storm-track measures are presented in Figure 10. In addition to the relatively weak polar jet, the tropopause zonal wind in this sector (Figure 10a) shows the sub-tropical jet over the winter half of the year. The polar jet is seen also at 850 hPa (Figure 10c), and at both levels it is near 50°N in June and, surprisingly, moves slightly north through the summer and stays there until its weakening at the end of winter. At both levels it is weakest in April and May.

397 In the extended winter season, September to March, the SD storm-tracks at the two levels show little change in latitude or magnitude. At both levels, the tracks have a broad 398 399 distribution in latitude, centred slightly south of the jet in the upper troposphere and north 400 of the jet in the lower troposphere. There are weak maxima in November and January. The weaker, more compact summer storm-track shows a slight poleward progression, keeping 401 402 its relationship to the jet. In the EA, the SD storm-track at the two levels show remarkably 403 little change of latitude with time of year, particularly in the extended winter season from 404 September to March. Throughout the year the lower tropospheric storm-track is centred 405 about 5° north of that in the upper troposphere.

The track densities (Figures 10b, d) also show a broad structure and latitudinal 406 movement is generally small but, in concert with the jet, there is a slight poleward 407 progression through the summer. The 250 hPa track density shows a strong summer 408 maximum as in the CA, but is quite uniform through the rest of the year. The mean 409 410 intensities have annual cycles similar to the other Atlantic sectors. Again it is the larger winter mean intensities that are reflected in the SD pictures. In the EA, the high intensities 411 412 at 250 hPa spread deep into the sub-tropics and into the region of the subtropical jet from 413 October to May. At both levels the higher intensities also spread into the polar region 414 except in the summer.

415 The highest contour in track density at 850 hPa (Figure 10d) indicates a rather flat distribution with latitude from September to March, with a hint of a double maximum from 416 417 November to March. The detailed monthly latitudinal profiles of track density at 850 hPa (not presented), show that for eight months of the year, November to May and also 418 419 September, there are indeed two weak maxima, near 54°N and 62°N. Further investigation 420 using the tracking of positive and negative V separately shows that the northern maximum is predominantly associated with southerly winds and the southern maximum with 421 northerly winds. 422

The track densities at 850hPa also show a marked track density maximum near 20<sup>o</sup>N from May to September indicative of the African Easterly waves in this sector (Thorncroft and Hodges, 2001). The similar signature seen in Figure 9 for the CA sector marks a continuation of these, with some becoming the tropical cyclone signature in the WA (Figure 7).

428 **4** Discussion

The focus for this study is the Pacific and Atlantic storm-tracks and these will be the subject of the discussion in this section. However, some discussion of the findings relevant to the Mediterranean storm-track, sub-tropical easterly waves and Arctic storm-tracks are given in the Supplementary Material, in sections SM.2, SM.3 and SM.4, respectively.

433 For the two major mid-latitude storm-tracks, the diagnostics presented here show many 434 similarities in behaviour from one sector to another over much of the Pacific and the 435 Atlantic, despite differences in detail. The annual cycles for the CP, EP, WA and CA in both 436 the upper and lower troposphere have significant similarities in behaviour. In amplitude (both of SD and mean intensity from tracking), each has a summer minimum and a relatively 437 438 flat distribution from October to April. The latter occurs despite the strong winter maxima in the westerly jets. The ubiquity of this result gives a more general basis for a theoretical 439 440 discussion of the relationship between jets and storm-tracks in winter than the more usual 441 focus on the mid-winter minimum in the Pacific. This discussion will have to take into account stability limitations in a strong jet (e.g. Nakamura, 1992; Christoph et al., 1997; 442 443 Chang, 2001; Deng and Mak, 2005; Nakamura and Sampe, 2002; Chang and Zurita-Gotor, 2007) and other processes, such as the varying contribution from diabatic heating 444 445 (Nakamura, 1992; Chang, 2001; Chang 2009).

In the winter, the storm-track structures are less coherent with the region of large storm intensities extending in latitude outside the region of maximum track density. In particular, in the upper troposphere high intensity storms are found in quite low latitudes in the central and eastern ocean basins. In Section 3.1.3 these have been identified with cut-off lows, and this identification may be applicable more generally.

Each storm-track shows a poleward movement from May to reach near 50°N in August and from October to December a return to near 40°N. Consequently, the autumn stormtrack is poleward of that in spring, consistent with the asymmetry in the zonally averaged wind discussed by Fleming et al (1987).

However, there are also significant quantitative differences between the two storm-455 456 tracks. A hypothesis raised from the present work is that the upstream seeding from East Asia and North America is the origin of many of these differences. The importance of 457 458 upstream seeding for the Pacific storm-track has been the subject of many earlier studies, e.g. Nakamura (1992), Hakim (2003), Orlanski (2005), Chang (2005), Robinson (2006), Penny 459 et al. (2010), and Chang and Guo (2012). Over East Asia the south-west extension of the 460 upper tropospheric Siberian storm-track to near 48°N where there is underlying baroclinicity 461 462 downstream of the northern side of the Tibetan Plateau leads to storm-track activity with maxima in the spring and autumn seasons which are not dominated by winter or summer 463 464 monsoons. The dominance of spring and autumn maxima in the storm-tracks weakens downstream, with winter values becoming more comparable, but can still be detected in 465 the East Pacific. The summer minimum is marked along the whole storm-track. 466

The possible importance of the East Asian maximum in storm activity near 33<sup>o</sup>N between 100<sup>o</sup>E and 130<sup>o</sup>E has been discussed by Hakim (2003) and Chang (2005). In this paper it has been seen that the lower tropospheric maximum in track density is present only in the first half of the year, and is likely to be related to the Spring Rains in Central China. It may be linked to the subtropical jet, though the upper tropospheric maximum that is very clear in vorticity tracking (HH1, Figure 1) is situated slightly north of it. The signature of this

473 maximum disappears by about 150°E, though as discussed by Chang (2005) there may be
474 interaction with storms on the more northerly track.

475 Turning to the Atlantic, in the sectors over eastern North America, the summer amplitude minima are less pronounced than in the Pacific sectors. In fact the track density 476 477 shows a marked peak in summer. Also in the upstream sectors, the strength of the storm-478 track, as given for example by SD, is quite flat from October to April. In addition, there is a marked latitudinal movement in the annual cycle. These features link closely to the annual 479 480 cycle in the latitude and magnitude of the baroclinicity over the North American continent. 481 The relative weakness of the summer minimum, with a maximum in track density at that time, and the flatness of the strength in the extended winter period are found downstream 482 along the Atlantic storm-track. The magnitude of the latitudinal cycle decreases to near zero 483 484 at the eastern end of the track, implying an annual cycle in the meridional tilt of the stormtrack, from SSW-NNE in the winter to almost zonal in the summer. 485

The track density at 250 hPa in the Pacific has a minimum in mid-winter, whereas that at 850hPa has a weak maximum then. This trend with height is consistent with the very recent paper of Schemm and Schneider (2018), where it was found that surface cyclones have a track density maximum in the mid-winter. In the Atlantic at 250hPa, there is little change in the track density over the extended winter, but 850hPa shows a weak mid-winter maximum as in the Pacific.

The annual cycle of the pdfs of lifetimes of the tracked features (not shown) have a similar behaviour in the Pacific and Atlantic, and at 250hPa and 850hPa. In each case there is a 3-day peak which is largest in winter and smallest in summer. In contrast, for life-times longer than 6 days, the summer is dominant and the winter weakest. This is consistent with

the longer periods in summer found for the Pacific by Chang and Yu (1999) and also for surface cyclones in Schemm and Schneider (2018). It is also consistent with the more marked summer minima generally seen here in the 2-6 day band pass SD pictures than in the tracking pictures.

There are many aspects of the rich Northern Hemisphere storm-track behaviour that 500 501 have been shown in HH1 and here that are not well-understood, and it is hoped that these 502 papers will provide a stimulant for further diagnosis of observations and theoretical 503 understanding of storm-tracks. An important extension of the present study will be to consider the inter-annual variability of the seasonal cycles of the storm-tracks and the 504 relationship with low frequency variability, in particular that associated with El Niño-505 Southern Oscillation (ENSO), North Atlantic Oscillation (NAO), Pacific Decadal Oscillation 506 507 (PDO) and Atlantic Multi-decadal Oscillation (AMO). It is also hoped that this pair of papers provides a basis for more detailed evaluation of the performance of climate models in 508 509 today's climate and diagnosis of their projections of storm-tracks in a changing climate.

#### 510 Acknowledgements

511 We thank Tim Woollings for provoking us into extending our previous analysis of NH 512 storm-tracks into other seasons. We also thank Paul Berrisford and the ECMWF Reanalysis 513 team for the provision of the basic data used in this paper. Finally, we than the Reviewers 514 for their helpful comments.

Figure 1. Track density (contours) and mean intensity (colour) for tracking of maxima in the 597 modulus of the meridional wind at 850hPa,  $|V_{850}|$ , for the winter season, DJF, with the 598 599 sectors considered in this study delineated by black lines for the main sectors discussed in 600 the text and yellow lines for the sectors shown in the supplementary material. Track density contours are every 5 with the dashed line at 12.5 in units of number per month per unit 601 area, where the unit area is equivalent to a  $5^0$  spherical cap, ~  $(10^3 \text{ km})^2$ . The intensity is in 602 units of m s<sup>-1</sup>. Mean intensity is suppressed for track densities below 1.0. 603 604 Figure 2. The storm-track in the Central Pacific (CP) sector as a function of the time of year 605 and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d) panels, respectively. The left column (a, c) is for the standard deviation (SD) of the 606 meridional wind (V), with (a) overlaid with U<sub>PV=2</sub> (contours starting at 20ms<sup>-1</sup> and interval 607 10ms<sup>-1</sup>) and (c) overlaid with U<sub>850</sub> (contours at 5ms<sup>-1</sup> and 10ms<sup>-1</sup>). The right column (b, d) 608 show tracking statistics for |V| maxima, and show track density (lines, ci of 2.0, long dashed 609 lines are 10.0 and short dashed lines are 20.0) and mean intensity (colour). The units for SD 610 and intensity are ms<sup>-1</sup> and for track density the number per month per unit area, where the 611 unit area is equivalent to a  $5^{\circ}$  spherical cap, ~  $(10^{3} \text{ Km})^{2}$ . 612

Figure 3. Summaries of the annual cycle of the storm-track maxima in the Central Pacific (CP) sector. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d) panels, respectively. The left column (a, c) is for the standard deviation (SD) of the meridional wind (V) and shows for each month the latitude of the maximum and its magnitude. The right column (b, d) is for tracking fields for |V| maxima, and shows for each month the latitude of the track density maximum and the mean intensity at that latitude.

The units of SD and intensity are m s<sup>-1</sup>. The colour coding for the months is shown in (b), and
the consecutive months from January to December are joined by straight lines.

621 Figure 4. The storm-track in the Western Pacific (WP) sector as a function of the time of year

and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d)

623 panels, respectively. The left column (a, c) is for the standard deviation (SD) of the

624 meridional wind (V) with (a) overlaid with  $U_{PV=2}$  (contours starting at 20ms<sup>-1</sup> and interval

10ms<sup>-1</sup>) and (c) overlaid with  $U_{850}$  (contours at 5ms<sup>-1</sup> and 7. 5ms<sup>-1</sup>(dashed)). The right

626 column (b, d) is for tracking statistics for |V| maxima, and show track density (lines) and

627 mean intensity (colour). The conventions are as in Fig.2.

Figure 5. The storm-track in the Eastern Pacific (EP) sector as a function of the time of year
and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d)

630 panels, respectively. The left column (a, c) is for the standard deviation (SD) of the

631 meridional wind (V) with (a) overlaid with  $U_{PV=2}$  (contours at 15 (dashed), 20, and 25ms<sup>-</sup>

<sup>1</sup>(dashed)) and (c) overlaid with U<sub>850</sub> (contours at 5ms<sup>-1</sup> and 7. 5ms<sup>-1</sup>(dashed)). The right

633 column (b, d) is for tracking fields for |V| maxima, and show track density (lines) and mean

634 intensity (colour). The conventions are as in Fig.2.

635 Figure 6. Summaries of the annual cycle of the storm-track maxima in the Eastern Pacific

(EP) sector. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d)

637 panels, respectively. The left column (a, c) is for the standard deviation (SD) of the

638 meridional wind (V) and shows for each month the latitude of the maximum and its

magnitude. The right column (b, d) is for tracking fields for |V| maxima, and shows for each

640 month the latitude of the track density maximum and the mean intensity at that latitude.

641 The conventions are as in Fig. 3.

Figure 7. The storm-track in the Western Atlantic (WA) sector as a function of the time of
year and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c,
d) panels, respectively. The left column (a, c) is for the standard deviation (SD) of the
meridional wind (V) with (a) overlaid with U<sub>PV=2</sub> (contours starting at 20ms<sup>-1</sup> and interval
10ms<sup>-1</sup>) and (c) overlaid with U<sub>850</sub> (contours at 5, 7. 5 (dashed), and 10 ms<sup>-1</sup>). The right
column (b, d) are the tracking statistics for |V| maxima, and show track density (lines) and
mean intensity (colour). The conventions are as in Fig.2.

649 Figure 8. Summaries of the annual cycle of the storm-track maxima in the Western Atlantic

650 (WA) sector. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d)

651 panels, respectively. The left column (a, c) is for the standard deviation (SD) of the

652 meridional wind (V) and shows for each month the latitude of the maximum and its

magnitude. The right column (b, d) is for tracking fields for |V| maxima, and shows for each

month the latitude of the track density maximum and the mean intensity at that latitude.

655 The conventions are as in Fig. 3.

Figure 9. The storm-track in the Central Atlantic (CA) sector as a function of the time of year

and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d)

panels, respectively. The left column (a, c) is for the standard deviation (SD) of the

659 meridional wind (V) with (a) overlaid with  $U_{PV=2}$  (contours starting at 20ms<sup>-1</sup> and interval

10ms<sup>-1</sup>) and (c) overlaid with  $U_{850}$  (contours at 5, 7. 5 (dashed), and 10 ms<sup>-1</sup>). The right

column (b, d) shows the tracking statistics for |V| maxima, and show track density (lines)

and mean intensity (colour). The conventions are as in Fig.2.

Figure 10. The storm-track in the Eastern Atlantic (EA) sector as a function of the time of
year and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c,

- d) panels, respectively. The left column (a, c) is for the standard deviation (SD) of the
- 666 meridional wind (V) with (a) overlaid with  $U_{PV=2}$  (contours at 15 (dashed), 20, and  $30 \text{ ms}^{-1}$ )
- and (c) overlaid with U<sub>850</sub> (contours at 5 and 7. 5 ms<sup>-1</sup> (dashed)). The right column (b, d) is
- 668 for tracking fields for |V| maxima, and show track density (lines) and mean intensity
- 669 (colour). The conventions are as in Fig.2.

### 671 Figures

672

Figure 1. Track density (contours) and mean intensity (colour) for tracking of maxima in the modulus of the meridional wind at 850hPa,  $|V_{850}|$ , for the winter season, DJF, with the sectors considered in this study delineated by black lines for the main sectors discussed in the text and yellow lines for the sectors shown in the supplementary material. Track density contours are every 5 with the dashed line at 12.5 in units of number per month per unit area, where the unit area is equivalent to a 5<sup>0</sup> spherical cap, ~ (10<sup>3</sup> km)<sup>2</sup>. The intensity is in units of m s<sup>-1</sup>. Mean intensity is suppressed for track densities below 1.0.

Figure 2. The storm-track in the Central Pacific (CP) sector as a function of the time of year 682 and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d) 683 panels, respectively. The left column (a, c) is for the standard deviation (SD) of the 684 meridional wind (V), with (a) overlaid with  $U_{PV=2}$  (contours starting at 20ms<sup>-1</sup> and interval 685 10ms<sup>-1</sup>) and (c) overlaid with U<sub>850</sub> (contours at 5ms<sup>-1</sup> and 10ms<sup>-1</sup>). The right column (b, d) 686 show tracking statistics for |V| maxima, and show track density (lines, ci of 2.0, long dashed 687 lines are 10.0 and short dashed lines are 20.0) and mean intensity (colour). The units for SD 688 and intensity are ms<sup>-1</sup> and for track density the number per month per unit area, where the 689 unit area is equivalent to a  $5^{\circ}$  spherical cap, ~  $(10^{3} \text{ Km})^{2}$ . 690

Figure 3. Summaries of the annual cycle of the storm-track maxima in the Central Pacific 693 694 (CP) sector. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d) 695 panels, respectively. The left column (a, c) is for the standard deviation (SD) of the 696 meridional wind (V) and shows for each month the latitude of the maximum and its 697 magnitude. The right column (b, d) is for tracking fields for |V| maxima, and shows for each 698 month the latitude of the track density maximum and the mean intensity at that latitude. The units of SD and intensity are m s<sup>-1</sup>. The colour coding for the months is shown in (b), and 699 700 the consecutive months from January to December are joined by straight lines.

Figure 4. The storm-track in the Western Pacific (WP) sector as a function of the time of year and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d) panels, respectively. The left column (a, c) is for the standard deviation (SD) of the meridional wind (V) with (a) overlaid with  $U_{PV=2}$  (contours starting at 20ms<sup>-1</sup> and interval 10ms<sup>-1</sup>) and (c) overlaid with  $U_{850}$  (contours at 5ms<sup>-1</sup> and 7. 5ms<sup>-1</sup>(dashed)). The right column (b, d) is for tracking statistics for |V| maxima, and show track density (lines) and mean intensity (colour). The conventions are as in Fig.2.

711

715 Figure 5. The storm-track in the Eastern Pacific (EP) sector as a function of the time of year

and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d)

panels, respectively. The left column (a, c) is for the standard deviation (SD) of the

718 meridional wind (V) with (a) overlaid with  $U_{PV=2}$  (contours at 15 (dashed), 20, and  $25 \text{ms}^-$ 

<sup>1</sup>(dashed)) and (c) overlaid with  $U_{850}$  (contours at 5ms<sup>-1</sup> and 7. 5ms<sup>-1</sup>(dashed)). The right

column (b, d) is for tracking fields for |V| maxima, and show track density (lines) and mean

721 intensity (colour). The conventions are as in Fig.2.

Figure 6. Summaries of the annual cycle of the storm-track maxima in the Eastern Pacific (EP) sector. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d) panels, respectively. The left column (a, c) is for the standard deviation (SD) of the meridional wind (V) and shows for each month the latitude of the maximum and its magnitude. The right column (b, d) is for tracking fields for |V| maxima, and shows for each month the latitude of the track density maximum and the mean intensity at that latitude. The conventions are as in Fig. 3.

Figure 7. The storm-track in the Western Atlantic (WA) sector as a function of the time of year and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c,

d) panels, respectively. The left column (a, c) is for the standard deviation (SD) of the

meridional wind (V) with (a) overlaid with  $U_{PV=2}$  (contours starting at 20ms<sup>-1</sup> and interval

 $10 \text{ ms}^{-1}$ ) and (c) overlaid with U<sub>850</sub> (contours at 5, 7. 5 (dashed), and 10 ms<sup>-1</sup>). The right

column (b, d) are the tracking statistics for |V| maxima, and show track density (lines) and

mean intensity (colour). The conventions are as in Fig.2.

740

Figure 8. Summaries of the annual cycle of the storm-track maxima in the Western Atlantic (WA) sector. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d) panels, respectively. The left column (a, c) is for the standard deviation (SD) of the meridional wind (V) and shows for each month the latitude of the maximum and its magnitude. The right column (b, d) is for tracking fields for |V| maxima, and shows for each month the latitude of the track density maximum and the mean intensity at that latitude. The conventions are as in Fig. 3.

Figure 9. The storm-track in the Central Atlantic (CA) sector as a function of the time of year and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c, d) panels, respectively. The left column (a, c) is for the standard deviation (SD) of the meridional wind (V) with (a) overlaid with  $U_{PV=2}$  (contours starting at 20ms<sup>-1</sup> and interval 10ms<sup>-1</sup>) and (c) overlaid with  $U_{850}$  (contours at 5, 7. 5 (dashed), and 10 ms<sup>-1</sup>). The right

column (b, d) shows the tracking statistics for |V| maxima, and show track density (lines)

and mean intensity (colour). The conventions are as in Fig.2.

760

Figure 10. The storm-track in the Eastern Atlantic (EA) sector as a function of the time of
year and latitude. The 250hPa and 850hPa levels are shown in the upper (a, b) and lower (c,
d) panels, respectively. The left column (a, c) is for the standard deviation (SD) of the
magnification (SD) and 20mer 1

meridional wind (V) with (a) overlaid with  $U_{PV=2}$  (contours at 15 (dashed), 20, and 30ms<sup>-1</sup>)

and (c) overlaid with  $U_{850}$  (contours at 5 and 7. 5 ms<sup>-1</sup> (dashed)). The right column (b, d) is

for tracking fields for |V| maxima, and show track density (lines) and mean intensity

769 (colour). The conventions are as in Fig.2.
