cloud turbulence are presented. Two contrasting case days are examined: a shallow “shower” case, and a “deep convection” case, exhibiting stronger and deeper updrafts. In our observations, ε generally ranges from $10^{-3} - 10^{-1} \text{ m}^2 \text{ s}^{-3}$, with the largest values found within, around and above convective updrafts. Vertical profiles of ε suggest that turbulence is much stronger in deep convection; 95th percentile values increase with height from $0.03 - 0.1 \text{ m}^2 \text{ s}^{-3}$, compared to approximately constant values of $0.02 - 0.03 \text{ m}^2 \text{ s}^{-3}$ throughout the depth of shower cloud. In updraft regions on both days, the 95th percentile of ε has significant ($p < 10^{-3}$) positive correlations with the updraft velocity, and the horizontal shear in the updraft velocity, with weaker positive correlations with updraft dimensions. The ε -retrieval method presented considers a very broad range of conditions, providing a reliable framework for turbulence retrieval using high-resolution Doppler weather radar. In applying this method across many observations, the derived turbulence statistics will form the basis for evaluating the parametrisation of turbulence in NWP models.

Keywords: Radar; Doppler spectrum width; turbulence; convection; eddy dissipation rate; clouds.

1 Introduction

The effects of turbulence on the structure and evolution of convective clouds remain unclear in observations and numerical weather prediction (NWP) models. The turbulent entrainment of dry environmental air into cumulus clouds has long been known to play an important role in their growth and decay (Blyth, 1993). The specific location of entrained air can have a varied and substantial impact on resulting air motions within the cloud (Blyth *et al.*, 1988). Turbulent mixing within clouds significantly impacts the microphysical processes governing the initiation of convective precipitation; the presence of turbulence accelerates cloud drop growth through increased rates of collision and coalescence (Grover and Pruppacher, 1985; Khain and Pinsky, 1995; Vohl *et al.*, 1999;

Observing turbulence in convective clouds

37 Falkovic *et al.*, 2002; Pinsky and Khain, 2002). Although there is much evidence for the effects of
38 turbulence on cloud processes, there remains uncertainty in their precise nature, and the implications
39 for cloud evolution.

40 In recent years, regional numerical weather prediction (NWP) has improved to sufficient
41 resolution that it is worthwhile abandoning the parametrisation of deep convective clouds, and,
42 instead, allowing the unstable growth of explicit convective clouds. However, it is not feasible to
43 forecast using resolutions sufficient to properly resolve all of the important features of the flow.
44 Hence such models are known as 'convection-permitting models' (CPMs, Clark *et al.*, 2016). Physical
45 processes occurring on scales below those resolved in CPMs, such as turbulence, remain
46 parametrised. CPMs generally adopt mixing-length-based turbulence closure schemes from Large-
47 Eddy Simulation (LES) models, such as the Smagorinsky-Lilly sub-grid scheme. It is not often clear
48 whether the assumptions implicit in these schemes (such as the ability of the model to resolve an
49 inertial sub-range of turbulence) are valid for CPMs, especially when using grid-lengths larger than
50 100 m. Model simulations show that the configuration of turbulence parametrisations can have a
51 profound effect on the characteristics of simulated clouds (e.g. Hanley *et al.*, 2015). Until we advance
52 our understanding of the effects of turbulence in observed clouds, justifiable attempts to evaluate and
53 improve these parametrisations are difficult to make.

54 To improve our understanding of turbulence in observed clouds for model evaluation,
55 observations of convective storm turbulence can be made with Doppler weather radar. By isolating
56 the turbulent component to the Doppler velocity spectrum variance, near-instantaneous observations
57 of turbulence can be made across large swathes of atmosphere. Turbulence retrieval with weather
58 radar has clear benefits over using methods such as aircraft or ascent measurements which can only
59 collect time-series information from single points in space. Radar retrieved fields of turbulence,
60 expressed for convenience in terms of the dissipation rate of turbulent kinetic energy, ϵ , can be used
61 to investigate relationships with storm strength and structure in a statistical sense for model
62 evaluation.

Observing turbulence in convective clouds

63 The accuracy to which ε can be derived using the Doppler variance method is dependent on the
64 accurate removal of variances associated with processes aside from inertial sub-range turbulence.
65 Due to this somewhat indirect approach, evaluation of the Doppler variance method has previously
66 been necessary through comparison of ε estimates with in situ measurements and other radar retrieval
67 techniques. Using Doppler weather radar, Labitt (1981) and Meischner *et al.* (2001) demonstrated
68 good agreement between ε derived from the Doppler variance method when compared with co-
69 ordinated aircraft measurements in convective storms. Brewster and Zrnic (1986) found a high level
70 of agreement between ε from Doppler variance and ε estimated from the “spatial spectra” method –
71 a method which involves taking the Fourier transform of a dataset of Doppler velocity measurements
72 sampled either along a single ray at a given time, or at a fixed range gate over a period of time.
73 Bouniol *et al.* (2003) performed a similar evaluation of the Doppler variance method using the spatial
74 spectra method with a vertically-pointing Doppler cloud radar. Point-for-point comparison of ε from
75 the two methods showed a high level of agreement, especially for larger values. They concluded that
76 the Doppler variance provides a reliable estimate of ε . The spatial spectra method itself has been
77 evaluated by Shupe *et al.* (2012), who analysed Doppler velocity time series sampled with a
78 vertically-pointing cloud radar in stratocumulus clouds. They found ε estimates from spatial spectra
79 to correspond well with aircraft and sonic anemometer measurements. Albrecht *et al.* (2016)
80 examined cloud-top entrainment processes in non-precipitating stratocumulus using vertically-
81 pointing Doppler cloud radar. In this study, estimates of ε were derived using both the Doppler
82 spectrum variance and the Doppler velocity power spectrum (Fang *et al.*, 2014), with good agreement
83 found between the two methods. Methods to retrieve ε at vertical incidence in (precipitating and non-
84 precipitating) stratocumulus using Doppler cloud radar are not well suited to retrieve ε with scanning
85 Doppler weather radar in precipitating convective clouds; as pertains to this study.

86 For scanning Doppler weather radar, the most significant contributor to Doppler variance aside
87 from turbulence is generally shear of the radial wind across the three dimensions of the beam (see
88 Section 5), which requires careful separation from turbulence before estimates of ε can be made.

Observing turbulence in convective clouds

Melnikov and Doviak (2009) present a detailed method to retrieve ε from the Doppler spectrum in vertical cross-sections through stratiform precipitation collected using an S-band Doppler weather radar. In their study, the radial and elevation shear components are calculated by least-squares fitting contiguous Doppler velocity measurements separately in each direction. A similar, though more sophisticated technique is applied in Section 5.3 to use linear regression to fit a 2-D linear velocity surface model (Neter and Wasserman, 1974) to Doppler velocities to evaluate shear over a spatial scale that we can specify and fix, guided by estimates of the inertial sub-range outer-scale (see Section 5.2). Using this method, we have been able to test the sensitivity of retrieved ε to the scale over which shear is calculated and removed (Section 5.5).

Melnikov and Doviak (2009) calculated the azimuthal (transverse) shear from velocity gradients between two adjacent scans separated by 2° . They found variances from azimuthal shear to be small compared to elevation shears in stratiform clouds. However, stronger horizontal shears are likely to be found in the convective clouds analysed in this application; in particular, along the edges of updrafts (e.g. Istok and Doviak, 1986). In the present application, our radar data includes one scan performed through one azimuth per cloud. Consequently, we have developed new methods to estimate the azimuthal shear component from the radial shear alone (Section 5.4), allowing for its variance contribution to be estimated when adjacent scans are not available.

Generally, past studies focus on single storm cases when using radar methods to investigate convective storm turbulence (e.g. Brewster and Zrnic, 1986; Istok and Doviak, 1986). Often, the contributions to the Doppler spectrum width from mechanisms aside from turbulence are either purely assumed to be negligible, or are shown to be negligible only for the purpose of the application. As a result, a comprehensive method to retrieve ε from radar fields under a wide range of conditions, and the statistical assessment of ε that such a method permits, have not been presented. In developing this comprehensive approach, comparison is made with the more limited approaches that have appeared in the literature.

Observing turbulence in convective clouds

In Sections 2 – 5 of this paper, we present methods to accurately determine ε from radar fields. This includes a summary of the conditions under which certain terms in the Doppler spectrum width equation can be neglected, and detailed methods for their calculation when they cannot. By applying this method across a dataset of radar observations, we have performed a statistical assessment of ε in convective storms; this is presented in Section 6.

2 Data and Methods

2.1 DYMECS – Radar observations with CAMRa

This investigation follows on from the Dynamical and Microphysical Evolution of Convective Storms (DYMECS) project (Stein *et al.*, 2014). The primary objective of DYMECS is to apply a statistical approach to investigate the dynamics, morphology and evolution of convective storms over southern England, both in radar observations and in high-resolution Met Office Unified Model (MetUM) simulations. An innovative track-and-scan method was used to obtain radar observations of hundreds of convective storms in 2011-2012. These were collected using the Chilbolton Advanced Meteorological Radar (CAMRa) located at the Chilbolton Observatory in Hampshire, UK. CAMRa is a 3 GHz (S-band) Doppler weather radar with dual-polarisation capability. The 25-m diameter antenna provides an angular beam-width of 0.28° . The narrow beam provides elevation, θ and azimuthal, φ resolutions of 100 m at 20 km range, and 500 m at 100 km range. In the radial direction, the pulse has a length of 75 m, however, this is averaged to 300 m in our observations.

Observations were collected by scanning with CAMRa in two modes: elevation scanning with RHIs (range-height indicator) and azimuthal scanning with PPIs (plan-position indicator). By alternating between these two modes, detailed observations of hundreds of convective storms were collected on 40 days between July 2011 and August 2012. These observations have been compared

Observing turbulence in convective clouds

with MetUM simulations to characterise storm morphology (Stein *et al.*, 2014) and convective updraft characteristics (Nicol *et al.*, 2015) in model and observations.

In Section 6, turbulence retrievals are analysed with corresponding fields of vertical velocity retrieved by Nicol *et al.* (2015) for DYMECS observations made on 20 April 2012 and 25 August 2012. These updraft velocities were estimated from the Doppler velocity by vertically integrating local changes in horizontal convergence under the assumption of flow continuity, accounting for the changes in density with height. The use of horizontal convergence to estimate vertical velocity removes the need to consider corrections for hydrometeor fall-speeds. The method required a zero-velocity boundary condition, either at the surface or cloud echo top. A weighted combination of velocity derived under both conditions was developed to minimise the vertical propagation of errors. In using only single-Doppler measurements, the omission of convergence in the direction perpendicular to the scanning plane led to a consistent under-estimation of the vertical velocity. To correct for this under-estimation, the suitable scaling for the vertical velocity was estimated from 500-m grid-length simulations of the MetUM for each case. These were made under assumptions that the simulated three-dimensional wind flows were suitably realistic and that the range of observed vertical velocities was represented in the model. The uncertainty in retrieved updraft velocities was estimated through point-for-point comparison of the scaled retrievals with model updrafts. For updraft velocities larger than 1 m s^{-1} (as analysed in this study), a root-mean-square difference of 2.5 m s^{-1} was found. It is likely that this uncertainty introduces scatter into the relationships between ε and characteristics of updraft velocity presented in Section 6, resulting in weaker measured correlations than may exist between ε and the true updraft strength.

2.2 Dissipation rates from CAMRa

Doppler weather radar, such as CAMRa, can be used to infer characteristics of atmospheric turbulence from observations of the radial velocity field. The mean Doppler velocity \bar{v} , is the

Observing turbulence in convective clouds

reflectivity-weighted average of radial point velocities found within a resolution volume (the volume of atmosphere observed by a single radar pulse, V_6). The Doppler spectrum variance σ_v^2 , estimated by CAMRa, is the variance in the velocity of reflectors within V_6 . Therefore, σ_v^2 includes velocity variance due to the turbulent motion of hydrometeors, among contributions from several other mechanisms. We assume that σ_v^2 can be decomposed into a sum of statistically independent variance contributions (Doviak and Zrnic, 1984).

$$\sigma_v^2 = \sigma_s^2 + \sigma_t^2 + \sigma_{TV}^2 + \sigma_\alpha^2 + \sigma_o^2 \quad (1)$$

Where σ_v^2 has contributions primarily from radial wind shear across the sample volume σ_s^2 , turbulence σ_t^2 , the distribution of hydrometeor fall-velocities σ_{TV}^2 , antenna rotation σ_α^2 , and hydrometeor oscillations σ_o^2 .

Using the theoretical framework presented by Frisch and Clifford (1974), we can calculate the eddy dissipation rate, ε from σ_t^2 . Details of turbulent motion cannot be directly measured from σ_v^2 . We can only infer σ_t^2 from σ_v^2 by accounting for all other variance contributions in (1), either by subtracting their variance from σ_v^2 , or by demonstrating that they are negligibly small compared to σ_t^2 .

The eddy dissipation rate is the rate of energy transfer through the inertial sub-range of isotropic turbulence. For calculations of ε to be accurate, σ_t^2 must consist only of velocity variance due to eddies with a spatial scale less than the largest scale of the inertial sub-range, Λ_0 . Ensuring this involves the careful separation of shear and turbulence, which is summarised in Section 5.

Once σ_t^2 has been determined, ε can be estimated from,

$$\varepsilon \approx \frac{1}{\alpha} \left[\frac{\sigma_t^2}{1.35A \left(1 - \frac{\gamma^2}{15} \right)} \right]^{\frac{3}{2}} \quad (2a)$$

Observing turbulence in convective clouds

$$\varepsilon \approx \frac{1}{\beta} \left[\frac{\sigma_t^2}{1.35A \left(1 + \frac{\xi^2}{15} \right)} \right]^{\frac{3}{2}} \quad (2b)$$

Where α (in metres) is the angular standard deviation of the two-way Gaussian beam pattern in the transverse (or elevation) direction (see σ_2 in Appendix S1), multiplied by the range from the radar. β is the standard deviation of the pulse in the radial dimension (assumed uniform; for CAMRa $\beta = 26.25\text{m}$). From this, $\gamma^2 = 1 - \left(\frac{\beta}{\alpha}\right)^2$ and $\xi^2 = 1 - \left(\frac{\alpha}{\beta}\right)^2$, and A is the universal constant of inertial sub-range turbulence, with a value of 1.6.

If $\alpha > \beta$, then (2a) is used, with (2b) to be used if $\alpha < \beta$. This distinction has often been ignored in past studies, which typically employ a simplified version of (2a) to determine ε (as stated in Doviak and Zrnic (1984)). For CAMRa, $\alpha > \beta$ at all ranges further than 17.9 km from the radar, so a similar approximation could be used. However, the application of (2a) and (2b) is straight-forward and any further approximation should be unnecessary.

Values of σ_v^2 generally range from $1 - 25 \text{ m}^2 \text{ s}^{-2}$ in our observations. In reality, the negligibility of terms in (1) depends on their value relative to σ_t^2 , and as a result, no fixed variance value will always be negligibly small. Assuming that turbulence is only significant when $\sigma_t^2 > 5 \text{ m}^2 \text{ s}^{-2}$ (this translates to $\varepsilon > 0.03 \text{ m}^2 \text{ s}^{-3}$ when $\alpha = \beta$), we choose a negligibility threshold σ_{neg}^2 , of $0.5 \text{ m}^2 \text{ s}^{-2}$ for the purpose of this application. Whereby, variance contributions that are less than σ_{neg}^2 can be neglected. We can test the impact of this selection on ε by determining the maximum combined variance of terms we may neglect. The variance contribution from σ_α^2 is small enough to be ignored completely ($\sigma_\alpha^2 < 0.01 \text{ m}^2 \text{ s}^{-2}$, see Section 4). We can calculate σ_s^2 directly (Section 5), so no element of this contribution is neglected, regardless of value compared to σ_{neg}^2 . However, contributions from σ_{TV}^2 and σ_o^2 are not simple to measure directly in our observations. Contributions from σ_{TV}^2 can be larger than σ_{neg}^2 for rain and hail (Section 3), while σ_o^2 is generally less than $0.25 \text{ m}^2 \text{ s}^{-2}$ (Section 4). A maximum error would be incurred in σ_t^2 of $0.75 \text{ m}^2 \text{ s}^{-2}$ when neglecting

Observing turbulence in convective clouds

206 σ_{TV}^2 at $0.5 \text{ m}^2 \text{ s}^{-2}$ (in the extreme case that hail or heavy rain is observed very close to the radar) and
207 σ_0^2 at $0.25 \text{ m}^2 \text{ s}^{-2}$. If $\sigma_t^2 = 5 \text{ m}^2 \text{ s}^{-2}$, this would translate to a 21.6% positive error in ε . The error
208 decreases as turbulence becomes more significant, to only 4.5% when $\sigma_t^2 = 25 \text{ m}^2 \text{ s}^{-2}$, and is
209 independent of the range of the σ_t^2 observation.

210 The range of ε values we can estimate using the Doppler spectrum width technique is determined
211 from the range of σ_v^2 values we can observe. This is related to the maximum ambiguous velocity
212 interval (Nyquist velocity) of the radar. Keeler and Passarelli (1990) state that reliable measurements
213 of the Doppler spectrum width can only be made between 0.02 – 0.2 of the Nyquist interval. CAMRa
214 has a Nyquist interval of 30 m s^{-1} , so we can only reliably observe σ_v between $0.6 - 6 \text{ m s}^{-1}$,
215 corresponding to σ_v^2 of $0.36 - 36 \text{ m}^2 \text{ s}^{-2}$. In the case where $\sigma_t^2 = \sigma_v^2$, we can determine the maximum
216 detectable range in ε from using this method with CAMRa. If observing such a range in σ_t^2 at a range
217 of 50 km, (the typical range of our storm observations), this would correspond to a maximum
218 detectable range in ε of $10^{-3} - 1 \text{ m}^2 \text{ s}^{-2}$.

219 The following three sections outline methods to assess the contribution of the non-turbulent terms
220 in (1). By either calculating these terms directly, or showing that they are negligibly small compared
221 to σ_t^2 , we can remove them from σ_v^2 . This allows us to find σ_t^2 as a residual velocity variance, and
222 then convert this to ε using (2a) and (2b).

223

224 **3 Doppler variance due to a distribution of hydrometeor fall velocities, σ_{TV}^2**

225 *3.1 Theoretical framework and derivation of spectral variance equations*

226 In a given sample volume V_6 , the presence of a distribution of hydrometeor diameters will lead to
227 a distribution of hydrometeor fall velocities. In the circumstance where the radar beam is not
228 perpendicular to hydrometeor velocity, this broadens the Doppler velocity spectrum. The observed
229 variance contribution, σ_{TV}^2 in (1), is at its maximum for a vertically pointing radar beam and decreases

Observing turbulence in convective clouds

with angle from zenith. Values of σ_v^2 include the total variance of hydrometeor velocity within the pulse volume. According to (1), the variance in hydrometeor velocity from a fall-speed distribution (σ_{TV}^2) is statistically independent from the variance in hydrometeor velocity resulting from air motions within the cloud (included in σ_s^2 and σ_t^2). Consequently, we require no assumptions regarding the vertical motion of air within the cloud when estimating σ_{TV}^2 .

Previous studies to estimate turbulence characteristics from Doppler velocity spectra typically assume σ_{TV}^2 to be negligible (e.g. Frisch and Clifford, 1974; Chapman and Browning, 2001; Meischner *et al.*, 2001; Melnikov and Doviak (2009)) unless observations were made at vertical incidence (Brewster and Zrnic, 1986). The expected variance due to σ_{TV}^2 is reduced significantly by scanning at lower elevations (often the reason σ_{TV}^2 is assumed negligible), however, this does not ensure the contribution is always negligibly small. Melnikov and Doviak (2009) neglected variance contributions from σ_{TV}^2 purely by assuming they remained below $0.2 \text{ m}^2 \text{ s}^{-2}$ when scanning at elevations below 20° through stratiform precipitation. However, results presented in Section 3.2 suggest σ_{TV}^2 from raindrops can reach $1 \text{ m}^2 \text{ s}^{-2}$ when scanning at 20° , though this remains dependent on radar reflectivity. The objectives of this section are to: provide a means to estimate σ_{TV}^2 when required, provide justification when neglecting σ_{TV}^2 contributions (showing that $\sigma_{TV}^2 < \sigma_{\text{neg}}^2$), and inform how future scanning strategies for turbulence retrieval can be tailored to ensure σ_{TV}^2 is always negligible.

For application to RHI radar observations, we classify two hydrometeor types based on the height of the 0°C isotherm, $z_{0^\circ\text{C}}$, which is estimated from the location of bright-band radar reflectivity in our observations. Though $z_{0^\circ\text{C}}$ varies for different DYMECS case days, the average height is ~ 1.5 km. For simplicity, we assume any reflectivity returned from below this level is due to liquid raindrops, and any reflectivity from above is due to ice aggregates. By making this simple distinction, we can estimate σ_{TV}^2 in all areas of an RHI scanning domain. In addition to aggregates and raindrops, graupel and hail are also important hydrometeor types, especially in convective clouds. We therefore

Observing turbulence in convective clouds

255 extend our analysis to assess the impact of hail, and consider the effects of graupel (treated as low-
256 density hailstones) in Section 3.3.

257 We assume the reflectivity for a given V_6 is dominated by one hydrometeor type, and that
258 hydrometeors are falling vertically downwards at terminal velocity relative to the vertical air motions
259 within the cloud. We assume hailstones are dry and are of solid ice with homogeneous density. For
260 hydrometeor mass calculations, we assume that both raindrops and hailstones are spherical.

261 To estimate the relative size of σ_{TV}^2 when compared to σ_v^2 , we can characterise σ_{TV}^2 as the variance
262 of the reflectivity-weighted mean fall velocity in V_6 as,

$$263 \quad \sigma_{TV_j}^2 = \overline{W_j^2} - \bar{W}_j^2, \quad (3)$$

264 where $\sigma_{TV_j}^2$ has units m^2s^{-2} , W is the reflectivity-weighted hydrometeor fall velocity, and j refers
265 to the hydrometeor type. We estimate $\overline{W_j^2}$ and \bar{W}_j^2 by evaluating the following integrals,

$$266 \quad \overline{W_j^2} = \frac{\int_0^\infty V_j(D)^2 M_j(D)^2 n_j(D) dD}{\int_0^\infty M_j(D)^2 n_j(D) dD}, \quad (4)$$

$$267 \quad \bar{W}_j^2 = \left(\frac{\int_0^\infty V_j(D) M_j(D)^2 n_j(D) dD}{\int_0^\infty M_j(D)^2 n_j(D) dD} \right)^2, \quad (5)$$

268 where $V_j(D)$, $M_j(D)$ and $n_j(D)$ are terminal velocity-diameter, mass-diameter and particle-size
269 distribution (DSD) relationships for hydrometeor j , respectively, and D is the hydrometeor diameter
270 in metres.

271 In (4) and (5), we assume that particle reflectivity is proportional to $M_j(D)^2$. We are in the
272 Rayleigh scattering regime, and hence this is a reasonable assumption for a 3 GHz radar. The integral
273 $R_j \int_0^\infty M_j(D)^2 n_j(D) dD$ provides the radar reflectivity in $\text{mm}^6 \text{m}^{-3}$. The term R_j is cancelled out in
274 (4) and (5), but is given by,

$$R_j = 10^{18} \frac{|K_j|^2}{|K_{\text{water}}|^2} \left(\frac{6}{\pi \rho_j} \right)^2, \quad (6)$$

where $|K_j|^2$ and ρ_j are the dielectric factor and density of hydrometeor j .

Terminal velocity-diameter relationships are commonly expressed as simple power laws,

$$V_j(D) = p_j D^{q_j}, \quad (7)$$

where V is the fall velocity and D is the drop diameter. For ice aggregates, D is the melted diameter.

Values of p and q for raindrops, ice aggregates and hailstones are taken from Atlas and Ulbricht (1977), Gunn and Marshall (1958) and Cheng and English (1982), respectively. These have been converted into S. I. units (See Table 1).

The hydrometeor mass M , as a function of particle diameter D , can be expressed in the form,

$$M_j(D) = a_j D^{b_j} \quad (8)$$

where M and D are in S. I. units.

We assume that the DSD of each hydrometeor class can be approximated by an exponential distribution of form given by Marshall and Palmer (1948).

$$n_j(D) = N_{0j} \exp(-\lambda_j D) \quad (9)$$

Where N_{0j} and λ_j are the intercept ($n_j(D = 0)$) and slope parameters, respectively, for hydrometeor type j . We consider this a suitable approximation; spectral broadening owing to a distribution in fall velocity has been shown to be nearly independent of the precise shape of the size distribution (Lhermitte, 1963).

For rain and ice aggregates, values of ρ , $|K|^2$, a , b and N_0 , are sourced from the UK Met Office

Observing turbulence in convective clouds

Unified Model microphysics scheme, as summarised in Stein *et al.* (2014) (See Table 1). For hail, we use an N_0 of $1.2 \times 10^4 \text{ m}^{-4}$ taken from Waldvogel *et al.* (1978). The sensitivity of $\sigma_{\text{TV}_j}^2$ to N_{0j} is discussed in Section 3.3.

To evaluate (3), we first substitute (7) – (9) into (4) and (5) using values from Table 1. By using a gamma function solution for the integrals in (3) we derive expressions for Doppler spectral variance contribution for the three hydrometeor varieties. At this point, they are functions only of DSD parameter, λ_j . Stein *et al.* (2014) provide an expression relating λ_j to radar reflectivity, Z_j ,

$$\lambda_j = \left(\frac{R_j a_j^2 N_{0j} \Gamma(1 + 2b_j)}{Z_j} \right)^{\frac{1}{1+2b_j}}, \quad (10)$$

where Z_j is the radar reflectivity of hydrometeor j and has linear units of $\text{mm}^6 \text{ m}^{-3}$.

Substituting (10) into the $\sigma_{\text{TV}_j}^2(\lambda_j)$ expressions and simplifying using values from Table 1, produces spectral variance equations for rain, ice aggregates and hail,

$$\sigma_{\text{TV}_{\text{rain}}}^2 = 0.62 Z^{0.191} \sin^2 \theta_{\text{el}}, \quad (11)$$

$$\sigma_{\text{TV}_{\text{agg}}}^2 = 0.029 Z^{0.119} \sin^2 \theta_{\text{el}}, \quad (12)$$

$$\sigma_{\text{TV}_{\text{hail}}}^2 = 1.7 Z^{0.143} \sin^2 \theta_{\text{el}}, \quad (13)$$

Where Z is in $\text{mm}^6 \text{ m}^{-3}$, $\sigma_{\text{TV}_j}^2$ has units of $\text{m}^2 \text{ s}^{-2}$ and θ_{el} is the elevation angle of the reflectivity observation measured from the surface. Together, these expressions can be used to estimate the Doppler variance contribution due to the distribution of hydrometeor fall speeds in V_6 .

3.2 Analysis of $\sigma_{\text{TV}_j}^2$

Reflectivity measurements in our observations with CAMRa are generally no less than -20 dBZ (the minimum detectable echo at 10 km range), and no more than 60 dBZ. In our application, we

Observing turbulence in convective clouds

therefore classify $\sigma_{TV_j}^2(Z_j = -20 \text{ dBZ})$ and $\sigma_{TV_j}^2(Z_j = 60 \text{ dBZ})$ as the minimum and maximum potential variances we encounter from each hydrometeor type.

Equations (11) – (13) show that $\sigma_{TV_j}^2$ increases with radar reflectivity and elevation angle of observation. Assuming a vertically pointing radar beam, and given Z_j in the range of -20 dBZ to 60 dBZ, $\sigma_{TV_{\text{rain}}}^2$ increases from 0.26 to 8.62 $\text{m}^2 \text{s}^{-2}$, $\sigma_{TV_{\text{agg}}}^2$ from 0.02 to 0.15 $\text{m}^2 \text{s}^{-2}$ and $\sigma_{TV_{\text{hail}}}^2$ from 0.90 to 12.53 $\text{m}^2 \text{s}^{-2}$. For DYMECS observations, RHIs scanned at a maximum elevation angle of 15°. Figure 1a displays (11) – (13) for a vertically pointing beam (black lines) and for 15° elevation (grey lines). Compared with a vertically pointing beam, if Z_j is sampled at 15° elevation, values of $\sigma_{TV_j}^2$ are respectively reduced by a factor of 14.

A maximum $\sigma_{TV_{\text{agg}}}^2$ of 0.15 $\text{m}^2 \text{s}^{-2}$ suggests that the contribution from ice aggregates is always less than σ_{neg}^2 . Assuming that ice aggregates constitute all hydrometeors above $z_{0^\circ\text{C}}$, then σ_{TV}^2 is negligible for all observations made above this level. For rain observations, which we assume are limited to below $z_{0^\circ\text{C}}$, the equivalent maximum of 8.62 $\text{m}^2 \text{s}^{-2}$ is comparably large, and so $\sigma_{TV_{\text{rain}}}^2$ cannot always be neglected. Using (11), we see $\sigma_{TV_{\text{rain}}}^2(60 \text{ dBZ}) < \sigma_{\text{neg}}^2$ for all rain observed at $\theta_{\text{el}} < 13.9^\circ$.

Under the circumstances that: $\sigma_{TV_{\text{agg}}}^2$ is always negligible, $\sigma_{TV_{\text{rain}}}^2$ is negligible when $\theta_{\text{el}} < 13.9^\circ$, $z_{0^\circ\text{C}}$ can be estimated, and hail is not present, we can describe the negligibility of σ_{TV}^2 in terms of a minimum range from the radar, R_{min} . For our application, R_{min} is simply the range from the radar a pulse reaches a height of $z_{0^\circ\text{C}}$ when transmitted at $\theta_{\text{el}} < 13.9^\circ$. In our RHI observations (where $z_{0^\circ\text{C}} \sim 1.5 \text{ km}$), σ_{TV}^2 is negligibly small everywhere at ranges further than 6.1 km from the radar. While σ_{TV}^2 can still be significant due to rain occurring nearer than R_{min} , below $z_{0^\circ\text{C}}$, it remains conditional on both Z_{rain} and θ_{el} . Observations used in this application were rarely made closer than 30 km from the radar, and so we neglect σ_{TV}^2 for rain and ice aggregates.

Observing turbulence in convective clouds

338 According to (13), hail can contribute more to σ_v^2 than rain. However, hail is generally a much
339 less common, more localised occurrence than rain. As a result, the detection of hail using retrieved
340 radar parameters (e.g. hail differential reflectivity H_{DR} , Depue *et al.* (2007)) is necessary before (13)
341 can be reliably applied. If observations do indeed include hail, (13) suggests that $\sigma_{TV_{hail}}^2$ (60 dBZ)
342 falls below σ_{neg}^2 for all hail observations made at $\theta_{el} < 11.5^\circ$. Due to the potential for hail presence
343 both above and below $z_{0^\circ C}$, negligibility based on range from radar is not stated. However, as the
344 minimum range of observations was 30 km, hail would need to be observed at 6 km altitude for
345 $\sigma_{TV_{hail}}^2$ to exceed σ_{neg}^2 , which is unlikely to have occurred.

346 Based on our threshold for negligibility σ_{neg}^2 , the estimation of $z_{0^\circ C}$, and under the assumptions
347 made in the derivation of (11) – (13), we can neglect variance contributions from σ_{TV}^2 in our
348 observations. Due to the dependence of (11) – (13) only on Z and θ_{el} , we expect this conclusion to
349 hold true for other scanning weather radars.

350

351 3.3 Sensitivity of $\sigma_{TV_{rain}}^2$ and $\sigma_{TV_{hail}}^2$ to assumptions

352 In this section, we examine the sensitivity of our results to some of the assumptions made in the
353 derivation of (11) and (13). For ice aggregates, no reasonable sensitivity testing has resulted in the
354 factor 3 increase in $\sigma_{TV_{agg}}^2$ required to even conditionally exceed σ_{neg}^2 . As a result, sensitivity tests
355 involving ice aggregates have been omitted from this discussion, and we conclude that $\sigma_{TV_{agg}}^2$ is
356 always negligible.

357 For rain and hail, we expect little uncertainty in the majority of values in Table 1. The first
358 potential source of uncertainty lies with the treatment of hail as dry with the density of solid ice. We
359 compare $\sigma_{TV_{hail}}^2$ when hailstones are dry with the density of solid ice (assumed in (13)), to low-
360 density and melting hailstones. Melting hailstones will possess a thin outer layer of liquid water,
361 appearing to the radar as large raindrops. To simulate this effect, we change the dielectric factor

Observing turbulence in convective clouds

362 $|K_{\text{hail}}|^2$, in (6) from 0.174 to 0.93. Resulting variance contributions are 21% lower than for dry
 363 hailstones for any given reflectivity. Assuming all hailstones below $z_{0^\circ\text{C}}$ have a liquid water layer,
 364 this reduction leads to $\sigma_{\text{TVhail}}^2(60 \text{ dBZ}) \approx \sigma_{\text{TVrain}}^2(60 \text{ dBZ})$ below $z_{0^\circ\text{C}}$. For observations made below
 365 $z_{0^\circ\text{C}} = 1.5 \text{ km}$, we find that $\sigma_{\text{TV}}^2 < \sigma_{\text{neg}}^2$ at all ranges further than 6.5 km from the radar, regardless
 366 of hydrometeor type. If we further consider melting hailstones consisting of low-density ice that is
 367 more consistent with graupel ($\rho_{\text{hail}} = 500 \text{ kg m}^{-3}$), this leads to a combined reduction in σ_{TVhail}^2 of
 368 34%, at which point $\sigma_{\text{TVhail}}^2(60 \text{ dBZ}) < \sigma_{\text{TVrain}}^2(60 \text{ dBZ})$, and we revert to neglecting σ_{TV}^2 at ranges
 369 further than 6.1 km.

370 A second source of uncertainty lies with the chosen values of N_0 ; respective values for rain and
 371 hail are assumed constant. For rain, we use $N_{0\text{rain}} = 8 \times 10^6 \text{ m}^{-4}$ from Marshall and Palmer
 372 (1948), who demonstrate its independence of rainfall intensity. The assumption of a constant $N_{0\text{hail}}$
 373 is not as safe as for raindrops as it depends on the largest hail diameter, D_{max} , and has been shown
 374 to vary from $10^3 - 10^5 \text{ m}^{-4}$ (Ulbricht, 1974). Our chosen value of $N_{0\text{hail}} = 1.2 \times 10^4 \text{ m}^{-4}$ from
 375 Waldvogel *et al.* (1978) is roughly in the centre of this range, and is very similar to values of $1.1 -$
 376 $1.4 \times 10^4 \text{ m}^{-4}$ presented by Ulbricht (1977). We test the effect of decreasing values of N_0 for rain
 377 and hail by an order of magnitude. This decrease is chosen to be large enough to roughly account for
 378 the maximum potential variability in N_0 . The result is a 55% increase in σ_{TVrain}^2 and a 39% increase
 379 in σ_{TVhail}^2 . Such a large increase in σ_{TVrain}^2 is unlikely given the confidence in our selection of $N_{0\text{rain}}$
 380 (Marshall and Palmer, 1948). However, the corresponding increase for σ_{TVhail}^2 is more likely realised
 381 given the stated uncertainty in $N_{0\text{hail}}$. Such an increase would imply that $\sigma_{\text{TVhail}}^2(60 \text{ dBZ}) < \sigma_{\text{neg}}^2$
 382 only if observed at $\theta_{\text{el}} < 9.8^\circ$. By instead increasing values of N_0 by an order of magnitude (not
 383 shown), we see a reduction in σ_{TVhail}^2 and σ_{TVrain}^2 of 36% and 28%, respectively.

384 A final source of uncertainty lies with the selected velocity-diameter relationship for hail,
 385 $V_{\text{hail}}(D)$. There is a broader diversity in these relationships in the literature than for rain; we assume

Observing turbulence in convective clouds

the $V_{\text{rain}}(D)$ power law provided by Atlas and Ulbricht (1977) to be accurate. Figure 1b compares $\sigma_{\text{TV}_{\text{hail}}}^2$ from (13) derived using $V_{\text{hail}}(D)$ from Cheng and English (1982), Ulbricht (1977), and Pruppacher and Klett (1978). As the $V_{\text{hail}}(D)$ proposed by Ulbricht (1977) involves the same exponent ($q = 0.5$) as that used for (13), the resulting effect is a 29% increase in $\sigma_{\text{TV}_{\text{hail}}}^2$ for all reflectivity owing to the different values of p . The $V_{\text{hail}}(D)$ relationship from Pruppacher and Klett (1978) however, involves $q = 0.8$. This leads to a change in exponent in (13), causing a decrease in $\sigma_{\text{TV}_{\text{hail}}}^2$ ($Z < 40$ dBZ) and an increase for $\sigma_{\text{TV}_{\text{hail}}}^2$ ($Z > 40$ dBZ). $\sigma_{\text{TV}_{\text{hail}}}^2$ (60 dBZ) is increased by 43%. Figure 1b suggests that the selection of $V_{\text{hail}}(D)$ can have a substantial and varied effect on $\sigma_{\text{TV}_{\text{hail}}}^2$ which somewhat limits how precisely we can state the conditions that allow us to neglect $\sigma_{\text{TV}_{\text{hail}}}^2$.

4 Spectral variance due to antenna rotation, σ_{α}^2 and hydrometeor oscillations, σ_o^2 .

The movements of the radar antenna while scanning will broaden the Doppler spectrum. Assuming a constant antenna scan rate α , in rad s^{-1} , the spectral variance contribution due to antenna rotation is provided by Doviak and Zrnic (1984),

$$\sigma_{\alpha}^2 = \left(\frac{\alpha \lambda \cos \theta_{\text{el}} \sqrt{\ln(2)}}{2\pi\theta_1} \right)^2, \quad (14)$$

where λ is the wavelength of the radar in metres, θ_{el} is the elevation angle from the surface, and θ_1 is the one-way half-power beam width in radians.

For CAMRa, $\lambda = 0.0975$ m and $\theta_1 = 5 \times 10^{-3}$ rad. During DYMECS, RHI and PPI observations were made using scan speeds of $\alpha_{\text{RHI}} = 7 \times 10^{-3} \text{ rad s}^{-1}$ and $\alpha_{\text{PPI}} = 35 \times 10^{-3} \text{ rad s}^{-1}$. The contribution from σ_{α}^2 is largest when scanning horizontally ($\cos(\theta_{\text{el}} = 0) = 1$); in this case $\sigma_{\alpha}^2 < 0.01 \text{ m}^2 \text{ s}^{-2}$ for both RHI and PPI observations, making a negligible ($\sigma_{\alpha}^2 < \sigma_{\text{neg}}^2$) contribution to σ_v^2 . Observations collected at non-zero elevations (up to 15° in DYMECS) would

only reduce the value of σ_α^2 . Equation (14) can be used simply to determine the contribution of σ_α^2 for radars with much faster scanning speeds.

The oscillation of hydrometeors can contribute to σ_v^2 , and has been speculated in Zrnic and Doviak (1989) to lead to over-estimation of ε . They find that σ_o^2 decreases with rain-rate, and generally does not increase above $0.25 \text{ m}^2 \text{ s}^{-2}$, so we neglect these contributions.

5 Spectral broadening due to shear of the radial wind, σ_s^2

5.1 Spectral variance equations for shear

Since we are justified in neglecting σ_{TV}^2 , σ_α^2 and σ_o^2 in (1) for DYMECS observations, we are left with Doppler variance contributions from shear and turbulence. We can derive the turbulent contribution from,

$$\sigma_t^2 = \sigma_v^2 - \sigma_s^2, \quad (15)$$

for use in (2a) and (2b) to calculate ε .

In (15), σ_s^2 represents the sum of Doppler variance contributions from the shear of the radial wind in the elevation θ , azimuthal (transverse across the beam) φ , and radial r , directions. Similar to σ_v^2 , σ_s^2 can be decomposed into a sum of statistically independent variance contributions from shear in each direction.

$$\sigma_s^2 = \sigma_{s\theta}^2 + \sigma_{s\varphi}^2 + \sigma_{sr}^2 \quad (16)$$

Various equations have been used in past literature to calculate $\sigma_{s\theta}^2$ and $\sigma_{s\varphi}^2$ that are not mutually consistent (e.g. Chapman and Browning, 2001). In Appendix S1, we provide a derivation of these equations that produces results in agreement with those stated in Doviak and Zrnic (1984). An expression for σ_{sr}^2 is also taken from Doviak and Zrnic (1984), assuming a rectangular transmitted pulse.

$$\sigma_{s\theta}^2 = \frac{(|S_\theta|R\theta_1)^2}{16 \ln 2} \quad (17)$$

$$\sigma_{s\varphi}^2 = \frac{(|S_\varphi|R\theta_1)^2}{16 \ln 2} \quad (18)$$

$$\sigma_{sr}^2 = \left(\frac{0.35|S_r|c\tau}{2} \right)^2 \quad (19)$$

Where R is the radial distance from the radar in metres, c is the speed of light in m s^{-1} , and τ is the pulse duration in seconds (for CAMRa, $\tau = 0.5 \mu\text{s}$). $|S_\theta|$, $|S_\varphi|$ and $|S_r|$ are shear magnitudes in s^{-1} , calculated from the mean Doppler velocity field. In (17) – (19), velocity and reflectivity gradients are assumed to be linear across V_6 . Equations (17) and (18) differ only in the shear involved, as the beam profiles in the θ and φ dimensions are the same.

In application to CAMRa, the variability of $\sigma_{s(\theta,\varphi,r)}^2$ with $|S|$ and R is illustrated in Figure 1c. For $|S_r|$ in the range of 0 to 0.02 s^{-1} , σ_{sr}^2 increases with $|S_r|^2$ from 0 to $0.28 \text{ m}^2 \text{ s}^{-2}$. As the pulse length is constant, σ_{sr}^2 does not vary with range. If $|S_r| < 0.027 \text{ s}^{-1}$ then $\sigma_{sr}^2 < \sigma_{\text{neg}}^2$, indicating that for our observations, σ_{sr}^2 is negligibly small except in cases of extreme shear. However, although σ_{sr}^2 is likely to be small, our chosen method of calculating shear (Section 5.3) permits direct measurement of $|S_r|$ to be made simply. We therefore include contributions from σ_{sr}^2 in σ_s^2 .

At 30 km range, for $|S_{\theta,\varphi}|$ in the range of $0 - 0.02 \text{ s}^{-1}$, $\sigma_{s(\theta,\varphi)}^2$ increases from $0 - 0.75 \text{ m}^2 \text{ s}^{-2}$. At 150 km range, this increase is to $18.7 \text{ m}^2 \text{ s}^{-2}$ when $|S_{\theta,\varphi}|$ is 0.02 s^{-1} . This suggests that, even at the minimum range of 30 km, if $|S_{\theta,\varphi}| > 0.016 \text{ s}^{-1}$, then $\sigma_{s(\theta,\varphi)}^2$ is always greater than σ_{neg}^2 for our data. Given that shears of this magnitude are quite possible (especially in the elevation direction), $\sigma_{s(\theta,\varphi)}^2$ will need to be considered for all of our observations. The high resolution of CAMRa means that radial velocity shear measured over small distances often result in negligible (less than $0.5 \text{ m}^2 \text{ s}^{-2}$) contributions to σ_v^2 , however, as illustrated, this is not true for shear of sufficient values. To ensure

accuracy in point-to-point values of ε , and consistency in application across full RHI scans, we measure and remove σ_s^2 at each point in our data. In Section 6.2, we provide and discuss an example retrieval for a shower cloud (Figure 8) in which σ_s^2 exceeds σ_{neg}^2 quite widely and represents a significant proportion of σ_t^2 . This example is used to highlight the potential for significant over-estimation of ε in our cases if shear corrections are neglected.

5.2 Separation of shear and turbulence - theory

The separation of shear and turbulence is a significant challenge. However, methods to make this distinction are guided by the framework employed to derive ε from σ_v^2 summarised in Section 2.2. The calculation of σ_s^2 is necessary to remove velocity variance contributions to σ_v^2 from outside the range of scales sampled by the radar. The scale over which to calculate shear (hereafter referred to as Λ_s) in (17) – (19), should ideally be equal to the largest scale of the inertial sub-range, Λ_0 . However, Λ_s should be strictly no larger than Λ_0 , otherwise the inclusion in σ_t^2 of variance from outside the inertial sub-range will lead to an over-estimation of ε .

Without the means to routinely estimate Λ_0 for each of the convective storm observations collected in DYMECS, we refer to past literature. Past studies have utilised Doppler spatial spectra and aircraft measurements to estimate Λ_0 in individual convective clouds (Battan, 1975; Knupp and Cotton, 1982; Brewster and Zrnica, 1986). They found that Λ_0 can be as large as 1.5 – 3 km. These estimates were made in severe thunderstorms/hailstorms with strong, large-scale circulations. In comparison, the convective storms constituting the DYMECS observations are generally much weaker, limiting how applicable these values are to our cases. We assume Λ_0 scales with the size of the largest eddy-generating mechanisms in a convective cloud, i.e. the main updraft circulation. If this circulation is shallow, we expect Λ_0 to be small as the downscale cascade to isotropic turbulence begins at a smaller eddy scale. As updraft heights on DYMECS case days generally ranged from 3 – 8 km (Nicol *et al.*, 2015), we assume $\Lambda_0 \sim 1$ km for this application. Chapman and Browning (2001) found a factor two change in Λ_0 to have very little effect on their resulting values of ε . However, this

Observing turbulence in convective clouds

involved assuming a Λ_0 of only 200 m for shallow shear layers, so we test the sensitivity of our retrieved ε to the value of Λ_s , summarised in Section 5.5.

5.3 Separation of shear and turbulence – linear velocity surface approach

The application of methods to distinguish σ_s^2 from σ_t^2 will depend on the relationship between the spatial resolution of the radar and Λ_0 . As long as the largest dimension of V_6 is less than Λ_0 , σ_t^2 can be used to estimate ε (Frisch and Clifford, 1974). As this is generally the case for a radar of CAMRa’s resolution, scanning deep convective clouds, σ_s^2 can then be determined from radial velocity shear calculated over enough contiguous V_6 volumes to constitute a spatial scale of Λ_0 .

To evaluate shear over a constant spatial scale in data with polar co-ordinates is not straightforward. With two-dimensional radar data, the most effective way to achieve this is to use least-squares regression to fit a velocity surface to Doppler velocity data. A suitable framework for this velocity surface is taken from Neter and Wasserman (1974), and has been applied in previous ε -retrieval studies (Istok and Doviak 1986, Meischner *et al.*, 2001). When applied to RHIs, the velocity surface is given by

$$V_i = V_0 + S_\theta l_{\theta_i} + S_r l_{r_i} + E_i \quad (20)$$

where

$$l_{\theta_i} = R_0(\theta_i - \theta_0) \quad ; \quad l_{r_i} = R_i - R_0$$

The range from the radar is given by R , θ is the elevation angle in radians, and (θ_0, R_0) is the centre point of the surface. V_i is the radial velocity at the point (θ_i, R_i) , and E_i is the velocity difference between the data and the surface. V_0 is the estimated central point velocity and S_θ and S_r are linear elevation and radial shears, respectively. l_{θ_i} and l_{r_i} are the elevation and radial distances between V_i and V_0 .

Observing turbulence in convective clouds

The parameters V_0 , S_θ and S_r are determined from the matrix operation,

$$\begin{bmatrix} V_0 \\ S_\theta \\ S_r \end{bmatrix} = \begin{bmatrix} n & \sum l_{\theta_i} & \sum l_{r_i} \\ \sum l_{\theta_i} & \sum l_{\theta_i}^2 & \sum l_{r_i} l_{\theta_i} \\ \sum l_{r_i} & \sum l_{\theta_i} l_{r_i} & \sum l_{r_i}^2 \end{bmatrix}^{-1} \begin{bmatrix} \sum V_i \\ \sum V_i l_{\theta_i} \\ \sum V_i l_{r_i} \end{bmatrix} \quad (21)$$

Centred to best approximation on a chosen Doppler velocity point, neighbouring data points are used to constitute (as closely as is possible) a Λ_s – by – Λ_s grid of data, G . Using velocities from G , (21) is used to compute linear shears S_θ and S_r , which are attributed back to the data point at the centre of G . By completing this process for all points in a scan, we obtain fields of S_θ and S_r , calculated over a fixed scale. If $\Lambda_s = \Lambda_0$, S_θ and S_r are representative of large eddies and/or velocity gradients in the ordered background flow. As a result, they can be used in (17) and (19) to determine $\sigma_{s\theta}^2$ and σ_{sr}^2 .

In applying (20) to our observations, we find that data located less than $\sim \frac{\Lambda_s}{2}$ from the edge of observed clouds will be lost in surface fitting. The grid G will only be partially filled with data for those V located on the periphery of reflectivity echoes, meaning (21) cannot be performed. The degree of data loss therefore increases with the value of Λ_s . As we can only account for σ_s^2 where shear can be measured, this data loss is imposed on retrieved fields of ε . Consequently, this limits our ability to investigate values of ε associated with entrainment processes near cloud edges. However, turbulence associated with entrainment into updrafts can still be retrieved in cases where updrafts are further than $\sim \frac{\Lambda_s}{2}$ from the edge of the radar echo (e.g. Figure 6c and 6f). Although we lose peripheral data, we benefit from the removal of noise in low reflectivity areas around cloud edges, which can develop large values of σ_v^2 . The 300-m range resolution of our observations restricts values of Λ_s to multiples of 300 m in order to include whole radial cells, and a minimum of 600 m to include at least two radial cells for the calculation of shear. Under these restrictions, assuming $\Lambda_0 \sim 1$ km, we select $\Lambda_s = 900$ m for our observations.

5.4 Variance from azimuthal shear, $\sigma_{s\varphi}^2$

When RHI or PPI scans are performed, the radial velocity field is observed in two dimensions, the radial direction and the scanning direction. However, these fields include data from three-dimensional sample volumes. In terms of RHIs, Doppler variance from azimuthal shear, $\sigma_{s\varphi}^2$ contributes to σ_v^2 , but we are unable to directly estimate it due to scanning in the elevation direction. Unless an adjacent RHI is performed, separated from the first by an angular distance comparable to the width of the beam, S_φ cannot be determined directly. As shown in Section 5.1, variance contributions from $\sigma_{s\varphi}^2$ cannot be ignored in our observations. To account for $\sigma_{s\varphi}^2$ in circumstances where it cannot be measured directly, we investigate statistical relationships between $|S_\varphi|$ and $|S_r|$ derived from PPI radar observations.

PPI scans were performed alongside RHIs scans on DYMECS case days. Doppler velocity fields from PPI scans can be differentiated in the radial and azimuthal directions to determine fields of $|S_\varphi|$ and $|S_r|$. By collecting many co-located pairs of $|S_\varphi|$ and $|S_r|$ from these fields, we attempt to parametrise $|S_\varphi|$ as a function of $|S_r|$. Using the result, $|S_r|$ found in RHIs can be used to estimate $|S_\varphi|$, and its uncertainty, allowing us to account for all components of σ_s^2 in RHI scans.

In order for relationships derived between $|S_\varphi|$ and $|S_r|$ to be of most benefit, we must impose they are calculated over a mutual spatial scale, consistent with that used to calculate $|S_\theta|$ and $|S_r|$ in RHIs, i.e. $\Lambda_s = 900$ m. To achieve this, we use a version of (20) tailored to PPI scans, where $S_\theta l_{\theta_i}$ is replaced by $S_\varphi l_{\varphi_i}$, and l_{φ_i} is the azimuthal distance between V_i and V_0 . By generating $|S_\varphi|$ and $|S_r|$ values for all V_6 across many PPIs, we could build a dataset consisting of co-located values of $|S_\varphi|$ and $|S_r|$ for statistical assessment.

Figure 2 shows the independent distributions of approximately 10^6 values of S_φ and S_r sourced from 31 PPIs taken on 20 April 2012 at varying elevations. S_φ and S_r are both approximately normally distributed. The combined two-dimensional distribution of S_φ and S_r is circular Gaussian,

547 approximately centred on $S_r = S_\phi = 0$. Once the magnitude of the values in the combined
 548 distribution is taken, which is the quantity relevant to σ_s^2 , $|S_r|$ is divided into contiguous intervals of
 549 width $1 \times 10^{-4} \text{ s}^{-1}$. For each of these, we extract the associated dataset of $|S_\phi|$, and generate its
 550 probability density function (PDF). Figure 3 demonstrates that the resulting PDFs are very well
 551 approximated by the gamma distribution, given for a random variable x , by (22).

$$\gamma(x|k, l) = \frac{x^{k-1} e^{-\frac{x}{l}}}{\Gamma(k) l^k} \quad (22)$$

553 Using (22), we can accurately simulate the change in the distribution of $|S_\phi|$ with $|S_r|$. For each
 554 $|S_r|$ interval, we extract the gamma distribution parameters k (shape) and l (scale) from the
 555 corresponding distribution of $|S_\phi|$. By numerically fitting functions to relationships between (k, l)
 556 and $|S_r|$, we define k and l in terms of $|S_r|$,

$$k = \begin{cases} |S_r|(A_1|S_r| + A_2) + A_3, & \text{if } |S_r| \leq 0.0017 \text{ s}^{-1} \\ B_1|S_r| + B_2, & \text{otherwise} \end{cases} \quad (23)$$

$$l = C_1|S_r| + C_2 \quad (24)$$

559 where coefficient values are provided in Table 2. For a given value of $|S_r|$, we use (23) and (24) to
 560 produce a PDF of $|S_\phi|$, and derive our estimate of $|S_\phi|$ as the mean of this distribution. For a gamma
 561 distribution, the mean is simply the product of k and l .

562 Figure 4 shows the change in median and inter-quartile range (IQR) percentiles of $|S_\phi|$ with $|S_r|$.
 563 Distributions of $|S_\phi|$ get broader with $|S_r|$. As a result, the size of the IQR, which provides a
 564 confidence interval for $|S_\phi|$, increases with $|S_r|$. The median values of $|S_\phi|$ increase with $|S_r|$
 565 according to (25) which was obtained by least-squares fitting a quadratic function to the median curve
 566 in Figure 4. Mean values of $|S_\phi|$ also increase with $|S_r|$, with values approximately 25% larger than
 567 the median.

$$|S_\phi|_{\text{med}} = |S_r|(D_1|S_r| + D_2) + D_3 \quad (25)$$

where coefficient values are provided in Table 2.

Using (23) – (25), $|S_\phi|$, and an estimate of its uncertainty, can be determined from $|S_r|$ alone. $|S_\phi|$ is then used in (18) to calculate its variance contribution, $\sigma_{S_\phi}^2$. We can now account for all components of σ_s^2 in (16), subtract σ_s^2 from σ_v^2 to find σ_t^2 using (15), and use σ_t^2 in (2a) and (2b) to determine ε .

5.5 Sensitivity of ε to Λ_s

To perform this sensitivity test, ε is determined in RHI scans of convective clouds using different values of Λ_s in methods to calculate σ_s^2 . We use 44 RHI scans performed on 25 August 2012 which provide 3.5×10^5 comparable data points for each Λ_s applied. For all scans, we retrieve $\varepsilon(\Lambda_s)$ where Λ_s is 600 m, 900 m, 1500 m, 2100 m, and 2700 m. As described in Section 5.3, the degree of peripheral data loss in velocity surface fitting increases with Λ_s . To ensure that we are comparing the same data across different Λ_s , the degree of data loss seen when $\Lambda_s = 2700$ m has been imposed on all other fields of ε for each scan.

Figure 5 displays the PDFs of $\varepsilon(\Lambda_s)$ using the combined data from all RHIs. It shows that the distribution of ε is largely insensitive to Λ_s , though there is a small increase in the likelihood of low values of ε (less than $0.01 \text{ m}^2 \text{ s}^{-3}$) with decreased Λ_s . When calculating shear over a smaller Λ_s , the shear magnitude, and therefore σ_s^2 , is likely to be higher. This means we remove more of σ_v^2 due to shear, and subsequently derive a lower ε , with the converse true if Λ_s is large. As the change in PDFs of ε is small in Figure 5, we can make rough estimations of Λ_0 (and therefore Λ_s) in the absence of direction measurements, without incurring large errors in ε .

6 Dissipation rate statistics in DYMECS observations

6.1 DYMECS case studies

Observing turbulence in convective clouds

By applying the methods detailed in Section 2 – 5 across many radar scans, we have performed a statistical assessment of ε in convective storms. We use two contrasting DYMECS days in 2012 as case studies; 20 April (hereafter the “shower” case) and 25 August (hereafter “deep convection” case). In the shower case, low pressure was situated on the east coast of the UK. Convective showers initiated over southern England in the late morning hours, and drifted north-eastwards through the day. In the deep convection case, low pressure was situated over the Irish Sea. Convective storms were more intense and widespread across southern England, with thunderstorms widely reported in the afternoon (Hanley *et al.*, 2015). Radar observations were collected using CAMRa in both cases, using a scanning algorithm that prioritised more active convective cells, guided in real time by Met Office network radar observations (Stein *et al.*, 2014). As this scanning strategy involved sequential scans of the same cells, a subset of these observations has been taken to include only independent convective storm RHI observations for analysis. This subset consists of 33 RHIs in the shower case, and 44 RHIs for deep convection, however, owing to the 200-km range of CAMRa, multiple convective storms were often present in single RHI scans. In the shower case, these observations show that convection grew to 6 km in height, with updraft vertical velocities w , typically ranging from 1 – 4 m s⁻¹. In the deep convection case, convection grew to 10 km with typical w ranging from 2 – 8 m s⁻¹ (Nicol *et al.*, 2015).

6.2 Example ε retrievals for convective showers and deep convection

Figures 6 and 7 display examples of retrieved ε for individual convective clouds on the shower and deep convection case days, respectively. These examples have been selected to reflect the typical convective storms observed on each day. Figure 6 depicts a convective shower of 6 km height, with a diffuse updraft region where w is 1 – 3 m s⁻¹ (Figure 6c), with a region of strong divergence present in the Doppler velocity above the updraft (Figure 6b). As shown in Figure 6f, ε typically ranges from 0.01 – 0.08 m² s⁻³ with the largest values found within the vicinity of the main updraft.

Observing turbulence in convective clouds

617 The example of deep convection displayed in Figure 7 has a depth of 10 km, and shows multi-cell
618 characteristics with numerous updraft-downdraft circulations present in Figure 7c. The dominant
619 updraft (~ 34 km from the radar) is narrower and much stronger than for the shower case, with w
620 ranging from $8 - 12 \text{ m s}^{-1}$. Divergence is again apparent in the Doppler velocity towards the upper
621 levels of the cloud (Figure 7b). Figure 7f indicates that turbulence is more intense and widespread
622 than for the shower case, with values of ϵ typically ranging from $0.03 - 0.3 \text{ m}^2 \text{ s}^{-3}$. These values are
623 again associated with the main updraft, with the most intense turbulence ($\epsilon > 0.3 \text{ m}^2 \text{ s}^{-3}$) found
624 towards the top of the cloud, above the updraft.

625 In many of the cloud cases that were examined to derive the statistics of ϵ presented later in this
626 section, values of σ_s^2 were small compared to σ_t^2 and largely remained below σ_{neg}^2 . The retrievals
627 presented in Figures 6 and 7 provide examples of this; values of $\sigma_s^2 > \sigma_{\text{neg}}^2$ were absent in the shower
628 cloud and were restricted to a small cluster of 36 pulse volumes in the deep cloud case. This region
629 is evident in Figure 7e, located from $7.5 - 8$ km in height at an approximate range of $33 - 34$ km.
630 Although σ_s^2 was significant in this region, values remained less than 15% of σ_t^2 suggesting that σ_s^2
631 could have been neglected in these two cloud examples without significantly over-estimating ϵ .

632 Shear corrections are, however, not negligible for all cloud cases considered, especially for those
633 located further from the radar. According to (17) and (18), variances from azimuthal and elevation
634 shear components increase with range squared. Figure 8 presents the ratio of σ_s^2 to σ_t^2 in an example
635 cloud observed between $90 - 115$ km from the radar on 20 April 2012. Within the region of $\sigma_s^2 >$
636 σ_{neg}^2 (black contour) values of σ_s^2 vary between $30\% - 70\%$ of σ_t^2 . Neglecting σ_s^2 in this region would
637 result in the over-estimation of mean ϵ by 52%. Given that clouds were commonly observed 100 km
638 (or further) from the radar, Figure 8 provides an example of the requirement to remove σ_s^2 in our data
639 to ensure accurate retrievals of ϵ .

640 By inspecting many retrievals of ϵ in convective clouds across two contrasting days of convection,
641 the rest of this section is focused on relating ϵ to convective storm characteristics in a statistical sense.

642

643 6.3 Vertical distribution of ϵ in convective clouds

644 Statistics have been collected for ϵ in vertical layers of 1-km depth from the subsets of RHI
 645 observations described in Section 6.1. Using this approach, we can assess the vertical distribution of
 646 ϵ in convective clouds (where $Z > -20$ dBZ), and see how this differs for showers and deep
 647 convection.

648 Figure 9 shows how the median, and 25th, 75th and 95th percentiles of ϵ change with height in the
 649 cloud; 0 – 6 km for showers, 0 – 10 km for deep convection. For showers and deep convection, the
 650 95th percentiles of ϵ (hereafter ϵ_{95}) from 0 – 1 km are approximately the same, at $\sim 0.025 \text{ m}^2 \text{ s}^{-3}$.
 651 For the shower case, this remains approximately constant with height, varying between 0.02 – 0.03
 652 $\text{m}^2 \text{ s}^{-3}$ and peaking at a height of 5 km. For deep convection, ϵ_{95} increases significantly with height,
 653 becoming twice as large as for the shower case at 6 km height ($0.05 \text{ m}^2 \text{ s}^{-3}$), and increasing to 0.1
 654 $\text{m}^2 \text{ s}^{-3}$ at 10 km height. The median ϵ is an approximately constant $0.01 \text{ m}^2 \text{ s}^{-3}$ throughout the 6-
 655 km depth of the shower cases. For the same depth of deep convective cloud, the median is almost
 656 identical to the shower case, and then increases from 0.01 – 0.03 $\text{m}^2 \text{ s}^{-3}$ from 6 – 10 km.

657 The 25th and 75th percentiles of ϵ follow a very similar pattern to this, indicating that from 0 – 6
 658 km the average intensity of turbulence is very similar for both cases. The reason for this is highlighted
 659 by Figure 6f and 7f; turbulence is locally intense, but a large proportion of the cloud area is only
 660 weakly turbulent in both cases ($\epsilon \leq 0.01 \text{ m}^2 \text{ s}^{-3}$). This was often the case throughout observations
 661 on both days which serves to explain why the bulk of ϵ values are so similar. Where the cloud is
 662 turbulent however, values of ϵ are much larger in deep convection with much stronger circulations,
 663 which is reflected in the notable difference in ϵ_{95} between the two cases.

664

665 6.4 ϵ in convective updraft regions

Observing turbulence in convective clouds

666 As we are most interested in the turbulent regions of individual convective clouds, and turbulence
667 in observations tends to be associated with convective updrafts (see Figures 6 and 7), we refine this
668 investigation to ε located only in convective updraft regions.

669 The following method has been selected in part to ensure it can be applied identically to numerical
670 model data in future investigations. To detect coherent updraft regions, a flood-fill algorithm is
671 applied to vertical cross-sections of w (T. Stein, personal communication), to automatically detect
672 contiguous regions with w above specified thresholds, and record their co-ordinates. By taking the
673 four spatial extremes of these co-ordinates, a box is drawn around an updraft – defined as an updraft
674 *region*. Updrafts are often irregular in shape in observations, so this approach includes some data
675 surrounding the updraft in the defined region. As a result, we benefit from including some
676 information about turbulence associated with an updraft, without it having to be co-located with
677 specific values of w .

678 Once updraft regions are defined, they are filtered by width and depth to avoid the inclusion of
679 very small, insignificant updrafts that are detected by the algorithm. For the shower case, we used a
680 minimum threshold w of 1 m s^{-1} , and a minimum depth of 2 km. For the deep convection case, we
681 used a minimum threshold w of 1.5 m s^{-1} , and a minimum depth of 3 km. In both cases, a minimum
682 updraft region width of 1.5 km was imposed. The lower thresholds for w and depth used in the shower
683 case were chosen due to the weaker, shallower updrafts observed on that day. Using this approach,
684 77 updraft regions were detected in the shower case, and 101 regions for deep convection. The co-
685 ordinates of each region can then be super-imposed on fields of ε for analysis.

686 Figure 10 displays scatter plots relating ε_{95} for each updraft region to its (a) 95th percentile of w
687 (hereafter w_{95}), (b) 95th percentile of the magnitude of the horizontal gradient in w , $\left|\frac{dw}{dx}\right|_{95}$, (c) updraft
688 width, and (d) updraft depth. In Figure 10a, we see that ε_{95} has a significant ($p < 10^{-3}$) positive
689 correlation with w_{95} for both showers ($r = 0.425$) and deep convection ($r = 0.594$). Correlations
690 with $\left|\frac{dw}{dx}\right|_{95}$ (Figure 10b) are marginally stronger than with w_{95} ($r = 0.517$ for showers, $r = 0.671$

Observing turbulence in convective clouds

691 for deep convection). This suggests that strong gradients in w are more important in generating
692 turbulence than w alone. Weaker positive correlations exist between ε_{95} and the width and depth of
693 updrafts for both showers ($r = 0.295$ for width, and $r = 0.314$ for depth), and deep convection
694 ($r = 0.309$ for width, and $r = 0.390$ for depth). This indicates that the intensity of turbulence is
695 not highly sensitive to the dimensions of the updraft. The consistency of correlations between the
696 two cases, albeit with a smaller range in variable values for the shower case, suggests that these
697 relationships may not be restricted to individual cases, or days of observation.

698 To produce Figure 11, all ε values in an updraft region are added to a distribution based on w_{95} .
699 By doing this, we can assess how the full distribution of ε changes with w_{95} in the two cloud types,
700 instead of just the largest values. These distributions are displayed in the form of cumulative density
701 functions (CDFs) for every 2 m s^{-1} interval in w_{95} . In both the showers and deep convection, a trend
702 towards a lower probability of small ε , and a higher probability of large ε is seen with w_{95} . In both
703 cases, small values of ε (less than $0.01 \text{ m}^2 \text{ s}^{-3}$) are approximately twice as likely to appear in updrafts
704 with $w_{95} < 4 \text{ m s}^{-1}$, than for those $w_{95} > 4 \text{ m s}^{-1}$. In the shower case, ε larger than $0.05 \text{ m}^2 \text{ s}^{-3}$
705 has a probability of less than 0.01 in all updraft regions ($w_{95} < 6 \text{ m s}^{-1}$); whereas for the same w_{95}
706 intervals of deep convection the probability is as large as 0.12. This indicates that stronger turbulence
707 is more likely to be found in deep convective clouds than for showers of the same updraft strength.
708 However, we see only a snapshot of information for each convective cloud; turbulent energy will
709 take time to reach dissipation scales, in which time updrafts could have weakened considerably. The
710 probability of large values of ε (more than $0.1 \text{ m}^2 \text{ s}^{-3}$) is 0 for the shower case, but as high as 0.05
711 for deep convection. When w_{95} is $2 - 4 \text{ m s}^{-1}$, the CDFs of ε are very similar for both cases, further
712 indicating that ε may be a function of storm characteristics independent of case, or day of observation.

713

714 7 Summary and Conclusions

Observing turbulence in convective clouds

715 A comprehensive analysis of processes contributing to the width of the Doppler velocity spectrum
716 has been performed, with the objective of developing a rigorous algorithm to estimate turbulence
717 intensity expressed as a dissipation rate.

718 New equations to quantify the spectral broadening effect due to a distribution of hydrometeor fall
719 speeds (σ_{TV}^2) have been presented for ice aggregates, raindrops and hail. We conclude that $\sigma_{TV_{agg}}^2$ is
720 always negligibly small, and $\sigma_{TV_{rain}}^2$ and $\sigma_{TV_{hail}}^2$ are negligible when observing at elevations lower
721 than 13.9° and 11.5° , respectively. We find that σ_{TV}^2 can be larger than $8 \text{ m}^2 \text{ s}^{-2}$ if scanning vertically
722 through heavy rain or hail, and recommend avoiding high-elevation scanning when attempting to
723 retrieve turbulence from the spectrum width.

724 Methods have been presented to remove contributions to σ_v^2 from shear over scales larger than
725 those sampled by the radar. This was achieved by evaluating shear over a constant spatial scale (Λ_s),
726 using linear velocity surface fitting techniques as employed in past studies. Resulting values of ε
727 have been found to be insensitive to Λ_s . To permit the estimation of ε from σ_t^2 , it is of key importance
728 that the largest dimension of V_6 is lower than Λ_0 .

729 To account for spectrum width contributions from shear in the azimuthal direction, we have
730 derived a new equation for the median azimuthal shear as a function of radial shear alone. This can
731 be used to account for 3-D shear broadening in 2-D radar scans, and can be used simply to further
732 improve the accuracy of retrieved ε . After noting incorrect equations for the calculation of σ_s^2 in the
733 literature, we conclude the correct equations are those derived in Appendix S1.

734 By applying the retrieval method across many observations on two contrasting DYMECS case
735 days, we have produced statistics of ε in convective clouds. Turbulence is generally much stronger
736 in deep convective cloud ($0.03 - 0.3 \text{ m}^2 \text{ s}^{-3}$) than in shower cloud ($0.01 - 0.08 \text{ m}^2 \text{ s}^{-3}$). In both
737 cases, the majority of cloud is generally weakly turbulent, with significant turbulence co-located
738 with, but not limited to, areas of shear and buoyancy. Strong turbulence is more widespread towards
739 the top of deep convective cloud, while vertical profiles of turbulence are approximately constant in

Observing turbulence in convective clouds

740 shower cloud. In updraft regions, turbulence is strongly correlated with updraft strength, and there is
741 evidence that gradients in the vertical velocity are more important in generating strong turbulence
742 than the updraft velocity alone. Turbulence is only weakly correlated with the spatial dimensions of
743 updrafts.

744 Our method has sourced, developed, and added to many decades of turbulence retrieval research
745 to form the most comprehensive approach to date. Though we have ultimately applied the method to
746 a specific radar and observational dataset, the considerations made in Sections 2 – 5 are suitably
747 general, forming a reliable framework for turbulence retrieval with other high-resolution radars
748 capable of sampling inertial sub-range turbulence.

749 Following directly from this research, we have collected new observations of convective clouds
750 with CAMRa, under an improved scanning strategy better suited to turbulence retrieval. By
751 performing multiple RHI scans separated by small azimuthal distances across clouds, we aim to
752 investigate the 3-D structures of turbulence in convective storms.

753 We have also used the results of this investigation to evaluate the performance of the
754 Smagorinsky-Lilly sub-grid scheme through direct comparisons with ε in high-resolution NWP
755 simulations of the observed cases. The degree to which our observations can be used more generally
756 to evaluate turbulence characteristics in CPMs (without the need to simulate the observed cases) is
757 not clear. However, at the very least, our observations can provide guidance for the typical
758 characteristics of ε in clouds for comparison with other high-resolution CPM simulations, given that
759 ε can be found as a diagnostic output from the turbulence parametrisation. To ultimately improve the
760 versatility of our results, we aim to extend our observations to more diverse cloud cases to assess the
761 degree to which our statistics are case-dependent.

763 Acknowledgements

Observing turbulence in convective clouds

This research was conducted with funding from the Natural Environment Research Council (NERC) under the SCENARIO programme. Acknowledgements go to Dr. John Nicol in providing vertical velocity retrievals for the case studies investigated, which have been invaluable to the analysis of turbulence in convective clouds. Further thanks go to staff at the Chilbolton Observatory for the technical support with data from CAMRa.

852 Figure Captions

853

854 **Figure 1.** (a) Change in $\sigma_{TV_j}^2$ for rain, ice aggregates and hail, with radar reflectivity Z_j , and elevation
855 angle, θ_{el} . Black lines refer to observations made at vertical incidence; grey lines at $\theta_{el} = 15^\circ$. (b)
856 The impact on $\sigma_{TV_{hail}}^2$ of using different $V_{hail}(D)$ relationships in the derivation of (13); (1) $p =$
857 142.6 , $q = 0.5$, (2) $p = 162.0$, $q = 0.5$, (3) $p = 359.0$, $q = 0.8$. Results are displayed for $\sigma_{TV_{hail}}^2$
858 sampled at vertical incidence ($\theta_{el} = 90^\circ$). (c) The change in $\sigma_{s\theta}^2$, $\sigma_{s\varphi}^2$ and σ_{sr}^2 (Eq. (17) – (19)) with
859 shear magnitude, $|S|$. Variances $\sigma_{s\theta}^2$, and $\sigma_{s\varphi}^2$ are displayed for ranges 30 km and 150 km, which are
860 roughly the minimum and maximum ranges of radar observations in the DYMECS data. Shears larger
861 than 0.02 s^{-1} were uncommon in our observations. In each panel, the threshold for negligibility σ_{neg}^2 ,
862 is plotted for reference as a dashed line at $0.5 \text{ m}^2 \text{ s}^{-2}$.

863

Observing turbulence in convective clouds

864 **Figure 2.** Independent distributions of 1×10^6 values of S_ϕ and S_r sourced from 31 PPI scans
865 performed on 20 April 2012.

866
867 **Figure 3.** Change in the PDFs of observed $|S_\phi|$ for three selected intervals of $|S_r|$ (solid lines).
868 Distributions of $|S_\phi|$ are well approximated by Gamma PDFs (22) (dashed lines). The width of each
869 $|S_r|$ interval is $1 \times 10^{-4} \text{ s}^{-1}$, and the interval of $|S_r|$ for each distribution is displayed in the figure
870 titles.

871
872 **Figure 4.** The change in the median, 25th and 75th percentile values of $|S_\phi|$ with $|S_r|$.

873
874 **Figure 5.** The insensitivity of distributions of ε to the scale Λ_s , over which shear is calculated for
875 σ_s^2 .

876
877 **Figure 6.** Example ε retrieval for an RHI scan of a convective storm performed on the 20 April
878 2012 (showers). Included is (a) radar reflectivity, (b) Doppler velocity, (c) vertical velocity, (d) total
879 Doppler variance, (e) Doppler variance due to shear, and (f) eddy dissipation rate displayed in \log_{10}
880 units. The grey contour outlines reflectivity returns of -20 dBZ.

881
882 **Figure 7.** Equivalent to Figure 6, an example retrieval of ε for an RHI scan of a convective storm
883 performed on the 25 August 2012 (deep convection).

884
885 **Figure 8.** The ratio of shear (σ_s^2) and turbulent (σ_t^2) contributions to Doppler variance in an example
886 shower cloud observed on 20 April 2012. The location of values of σ_s^2 that exceed σ_{neg}^2 is indicated
887 by the black contour. In this example, neglecting σ_s^2 in the contoured region results in the
888 considerable over-estimation of mean ε by 52%.

Figure 9. Comparison of the vertical distribution of various percentiles of ε in convective clouds ($Z > -20$ dBZ) on 20 April (showers) and 25 August (deep convection), 2012. Percentiles for each 1 km layer are plotted at the midpoint of that layer.

Figure 10. Scatter plots comparing the 95th percentile of ε for each updraft region ε_{95} , on 20 April (showers) and 25 August (deep convection), 2012, to the following corresponding statistics: (a) the 95th percentile of vertical velocity w_{95} , (b) the 95th percentile of the magnitude of the horizontal gradient in vertical velocity $\left|\frac{dw}{dx}\right|_{95}$, (c) the updraft width, and (d) the updraft depth.

Figure 11. The change in the cumulative density function (CDF) of ε in updraft regions with different 95th percentile values of w (w_{95}) for 20 April 2012 shower updrafts (black lines) and 25 August 2012 deep updrafts (grey lines). Values of w_{95} did not exceed 6 m s^{-1} in any shower updraft region. Values of w_{95} smaller than 2 m s^{-1} were not found in any deep updraft region.
