Abstract

Particle filters are fully non-linear data assimilation methods and as such are highly relevant. While the standard particle filter degenerates for high-dimensional systems, recent developments have opened the way for new particle filters that can be used in such systems.

The implicit equal-weights particle filter (IEWPF) is an efficient approach which avoids filter degeneracy because it gives equal particle weights by construction. The method uses implicit sampling whereby auxiliary 15 vectors drawn from a proposal distribution undergo a transformation before they are added to each particle.

In the original formulation of the IEWPF, the proposal distribution 18 has a gap causing all but one particle to have an inaccessible region in 19 state space. We show that this leads to a systematic bias in the pre-20 dictions and we modify the proposal distribution to eliminate the gap. 21 22 We achieved this by using a two-stage proposal method, where a single variance parameter is tuned to obtain adequate statistical coverage properties of the predictive distribution. We discuss properties of the implicit
mapping from an auxiliary random vector to the state vector, keeping in
mind the aim of avoiding particle resampling. The revised filter is tested
on linear and weakly nonlinear dynamical models in low-dimensional and
moderately high-dimensional settings, demonstrating the suiccess of the
new methodology in removing the bias.

30 1 Introduction

Geophysical models involving numerical simulations of processes unfolding in 31 space and time often take the form of state space models with non-linear dy-32 namics and millions of state variables. As the evolution of such systems is 33 sensitive to initial conditions and boundary conditions, which are almost never 34 known precisely, the actual system state is generally uncertain. Model error, 35 failure of the numerical model to faithfully represent the simulated process, also 36 contributes to system state uncertainty. If observations of the modelled sys-37 tem are available, then incorporating information from these into the model 38 through data assimilation can mitigate uncertainty and lead to more accurate 39 predictions. 40

Data assimilation in a Bayesian setting begins with a prior probability distribution representing background knowledge about the unknown state variables. The relationships between states and observations are represented by conditional probability distributions referred to as the likelihood. Combining the prior distribution and likelihood according to Bayes' theorem yields a posterior distribution of the state conditional on the observations. When this is done over time, data assimilation conditions the dynamical model to data.

48 Variational data assimilation methods like 3D-Var and 4D-Var use optimi-

sation to locate the posterior mode (Asch et al., 2016; Van Leeuwen et al., 2015; 49 Fletcher, 2017). While variational data assimilation methods do not necessarily 50 characterise the spread of the posterior distribution, an estimate of the poste-51 rior covariance is available via the inverse of the Hessian evaluated at the mode. 52 More direct uncertainty quantification is possible with ensemble-based data as-53 similation methods such as the many variants of the ensemble Kalman filter 54 (EnKF), see e.g. Evensen (2009). However, the EnKF uses linear updating and 55 implicitly assumes that the state distribution and likelihood are Gaussian. This 56 limits the applicability of EnKF variants to only mildly non-linear dynamical 57 models. 58

Particle filters (PFs), see e.g. Doucet et al. (2000), most of which are based 59 on importance sampling, have no assumptions of linearity or Gaussianity. They 60 work by propagating particles, or model realizations, forward in time via a 61 forecast step and then weighting particles according to the likelihood, so that 62 the resulting weighted ensemble of particles represents the posterior probability 63 density. Some PF variants modify the forecast step by drawing particles from 64 a proposal distribution instead of the forward model (e.g. Doucet et al., 2000; 65 Van Leeuwen, 2009; Morzfeld et al., 2012; Van Leeuwen et al., 2015). This is then 66 accounted for in the weighting step. PFs are appealing in large part because 67 they are free of distributional assumptions and will, given enough particles, 68 correctly sample the posterior distribution even when applied to highly non-69 linear dynamical models. In practice, when the number of particles is limited, 70 PFs are subject to the curse of dimensionality and can be relied on for correct 71 sampling only when state and observation dimensions are low to moderate. 72 Applied to high-dimensional data assimilation tasks, PFs tend to suffer from 73 filter degeneracy in the form of sample impoverishment. That is, the distribution 74 of particle weights, which is initially uniform, quickly begins to concentrate 75

⁷⁶ around, and eventually collapses onto, a small subset of particles, effectively
⁷⁷ reducing the ensemble size (Snyder et al., 2008).

There have been several approaches trying to combine strengths from PFs 78 with EnKF approaches. Stordal et al. (2011) constructed a useful Gaussian 79 mixture approximation to the predicted distribution at each step, bridging the 80 EnKF update with a special kind of PF updates. Rezaie and Eidsvik (2012) 81 shrinked the PF update towards the EnKF update, also relying on Gaussian 82 mixture models, and tuned the shrinkage parameter to avoid degeneracy while 83 maintaining reasonable statistical properties. Frei and Künsch (2013) applied 84 a tuning parameter in the exponent of the likelihood part, where parts of the 85 data (with larger variance) are used in an EnKF update, while the remaining 86 part is used in a PF step. In principle, these approaches have the non-linear 87 appeal of PFs, but automatized tuning tends to give results closer to the EnKF 88 output for high dimensional systems and moderate particle sizes (Stordal et al., 89 2011). 90

Although in theory filter degeneracy issues can be remedied by increasing the 91 number of particles, computational limitations restrict ensemble sizes to around 92 100 particles in many data assimilation applications (Van Leeuwen, 2009). What 93 is desired in such cases is a PF variant that is resistant to filter degeneracy and 94 maintains a resonable particle weight distribution when applied to nonlinear 95 dynamical systems. Unlike the standard PF, such a filter might be a viable 96 solution for nonlinear and high dimensional data assimilation despite having to 97 operate with only a moderate number of particles. 98

The equivalent weights particle filter (EWPF, Van Leeuwen, 2010; Ades and Van Leeuwen, 2013) is a non-linear data assimilation approach which uses a proposal distribution constructed to give equal weights in the update step, thus avoiding particle degeneracy. Depending on the specifics of the proposal density used, some or all particles may need to be resampled to maintain exact equalitybetween weights.

The implicit equal-weights particle filter (IEWPF), introduced by Zhu et al. 105 (2016), similarly prevents filter degeneracy by constructing the proposal dis-106 tribution so that the weights are uniform. The IEWPF combines the implicit 107 sampling framework of Chorin et al. (2013) with the equal-weights idea from 108 Ades and Van Leeuwen (2013). By the implicit construction no parameter tun-109 ing is required. However, the approach tends to give biased results, particularly 110 for moderate state dimensions, because its construction yields a proposal density 111 for particle updates that is zero on parts of state space. 112

The new contributions of the current paper are first a demonstration that 113 this bias is systematic, and leads to underestimation of the filter variance. Sec-114 ondly, we modify the IEWPF to remedy some of the deficiencies of the proposal 115 distribution under the original IEWPF formulation, specifically to eliminate the 116 gap in state space described by Zhu et al. (2016) and to reduce the mismatch 117 between the reported and actual prediction variance of the ensemble represen-118 tation of the posterior probability density. Our suggested modification achieves 119 this by introducing an additional perturbation of each particle in the update 120 step of the filtering algorithm. Adjusting the scale of this perturbation enables 121 calibration of ensemble spread without compromising particle weight equality. 122 Additionally, the revised IEWPF can be applied to systems of any dimension. 123 This is in contrast to the original IEWPF, which relied on an approximation 124 that is only valid when the state dimension is large. 125

The new filter is a substantial improvement of the original IEWPF as it provides a way to mitigate the bias in the original method. Still, it should be noted that as with the original IEWPF, the emphasis is on handling non-Gaussianity resulting from a nonlinear dynamical model rather than a nonGaussian likelihood. Allowing a nonlinear observation operator does not pose a fundamental problem but part of the analytical development involving the incomplete γ functions would not be possible, and solutions to the nonlinear equations would rely more on iterative methods. Such an extension is outside the scope of the this work.

This paper is organized as follows: In Section 2 the original single-stage IEWPF algorithm is described. In Section 3 the new two-stage IEWPF is presented. In Section 4 a linear example and a non-linear Lorenz96 example are studied.

¹³⁹ 2 Implicit equal-weights particle filter (IEWPF)

In this section we describe the main ideas and building blocks of the IEWPF algorithm. Some properties and challenges of this algorithm are discussed. A modified version of the filter is then described in Section 3.

¹⁴³ 2.1 Problem description and background

Consider a dynamical system with an N_x -dimensional state vector \mathbf{x}^n , $n = 0, 1, \ldots, n_t$. Set initial distribution $\mathbf{x}^0 \sim N(\boldsymbol{\mu}, \mathbf{B})$, denoting an N_x -dimensional Gaussian distribution with mean vector $\boldsymbol{\mu}$ and covariance matrix \mathbf{B} . Given the state at time t_{n-1} the state at time t_n is given by

$$\mathbf{x}^n = \mathcal{M}(\mathbf{x}^{n-1}) + \mathbf{u}^n,\tag{1}$$

where \mathcal{M} denotes forward integration of the dynamical system, and $\mathbf{u}^n \sim N(\mathbf{0}, \mathbf{Q})$ represents additive model error that we assume to be independent over time.

Suppose that at times $m \in \{1, 2, ...\}$ an observation vector $\mathbf{y}^m \in \mathbb{R}^{N_y}$ is

¹⁵² available. The relationship between the state and observation vectors is

$$\mathbf{y}^m = \mathbf{H}\mathbf{x}^m + \mathbf{v}^m. \tag{2}$$

Here, **H** is a size $N_y \times N_x$ linear observation operator and $\mathbf{v}^m \sim N(\mathbf{0}, \mathbf{R})$ 153 represents additive observation error. In this article we will consider observation 154 operators which simply select certain elements of the state vector, but operations 155 like averaging and convolution of state vector elements are also possible. We 156 assume that the error terms are independent over time, and independent of the 157 error terms in the dynamical system model. Furthermore we will assume in the 158 remainder of this article that observations are available at every time step n, so 159 that the above notation may be simplified by letting m = n. 160

The filtering problem consists of estimating the current state \mathbf{x}^n given all 161 available observations up to time n. We denote the set of observations by $\mathbf{y}^{1:n}$. 162 The filtering probability density function is $p(\mathbf{x}^n | \mathbf{y}^{1:n})$, and this is computed 163 sequentially for $n = 1, 2, \ldots$ The PF (Gordon et al., 1993) represents the 164 filtering distribution at every stage n by a size N_e ensemble of state realizations 165 $\mathbf{x}_{i}^{n}, i = 1..., N_{e}$, called particles. Weights $w_{i}^{n}, i = 1, ..., N_{e}$, are assigned to 166 each particle. A particle's weight is proportional to the likelihood of all data 167 along its sample path. It is updated sequentially using the multiplicative factor 168 $p(\mathbf{y}^n | \mathbf{x}_i^n).$ 169

One major problem affecting PF methods is sample degeneracy, also known as sample impoverishment. This happens when the distribution of weight over particles becomes more unequal with every iteration. Eventually this leads to a situation where almost all weight is concentrated on a single particle, so that the effective sample size is much smaller than the nominal ensemble size, and the usefulness of the resulting ensemble is very limited. To avoid this behaviour it is of interest to minimise the variance of the weights with respect to the filtering distribution. The weights could be reset by including various kinds of resampling of particles at different stages, but this is usually not enough to avoid degeneracy in high-dimensional state space models.

Some PF variants employ importance sampling (Van Leeuwen, 2009), whereby particle updates are drawn from a proposal probability density function, or importance function, $q(\mathbf{x})$. Proposal densities are typically chosen to allow easy sampling and pointwise evaluation. The choice of proposal distribution can also affect the overall efficiency of the algorithm. For consistent results the particle weights are multiplied by the ratio of the target density to the proposal density

$$\frac{p(\mathbf{x}^n|\mathbf{y}^{1:n})}{q(\mathbf{x}^n)}.$$
(3)

According to Doucet et al. (2000), among potential importance functions of the form $q(\mathbf{x}^n) = q(\mathbf{x}^n | \mathbf{x}_i^{n-1}, \mathbf{y}^n)$, the one which minimises the particle weight variance is the conditional distribution $p(\mathbf{x}^n | \mathbf{x}_i^{n-1}, \mathbf{y}^n)$, referred to as the optimal proposal density (OPD, Snyder et al., 2015). Ades and Van Leeuwen (2013) showed that a PF using the optimal proposal density as an importance function will degenerate slower than the standard SIR PF, but the exponential dependence on the size of the system remains the same.

With our modeling assumptions, this OPD is Gaussian. At stage n, and for every particle $i = 1 \dots, N_e$, its mean and covariance matrix, denoted by $\mathbf{x}_i^{n,a}$ and **P** respectively, are given by

$$\mathbf{x}_{i}^{n,\mathbf{a}} = \mathcal{M}(\mathbf{x}_{i}^{n-1}) + \mathbf{Q}\mathbf{H}^{T}(\mathbf{H}\mathbf{Q}\mathbf{H}^{T} + \mathbf{R})^{-1}(\mathbf{y}^{n} - \mathbf{H}\mathcal{M}(\mathbf{x}_{i}^{n-1})), \qquad (4)$$

196 and

$$\mathbf{P} = (\mathbf{Q}^{-1} + \mathbf{H}^T \mathbf{R}^{-1} \mathbf{H})^{-1}.$$
 (5)

¹⁹⁷ 2.2 Single-stage IEWPF

The proposal density can be constructed in various ways. We will now discuss the implicit scheme used in the IEWPF. This implicit sampling is realised by centering the proposal distribution on the mode of the OPD for each particle, and adding a random perturbation vector which is pre-multiplied by the square root of the OPD covariance matrix (5) and by a particle-specific scale factor $\alpha_i^{1/2}$.

Mathematically, the updated state of particle i is computed according to

$$\mathbf{x}_i^n = \mathbf{x}_i^{n,a} + \alpha_i^{1/2} \mathbf{P}^{1/2} \boldsymbol{\xi}_i^n, \tag{6}$$

where the random vector $\boldsymbol{\xi}_{i}^{n} \in \mathbb{R}^{N_{x}}$ is drawn from the proposal distribution $q(\boldsymbol{\xi}_{i}^{n})$, which is specified as $N(\mathbf{0}, \mathbf{I}_{N_{x}})$. With $\alpha_{i} = 1$ this scheme is equivalent to drawing samples from the OPD. When $\alpha_{i} \neq 1$, the corresponding sampling distribution is either compressed or extended relative to the OPD. Note that α_{i} will change over time steps, but for notational convenience we have suppressed the superscript n.

By selecting α_i judiciously one can gain flexibility in the algorithm and avoid particle degeneracy, for instance by aiming for equal weights like we do here. The weight of particle *i* is given by

$$w_i^n = w_i^{n-1} \frac{p(\mathbf{x}^n | \mathbf{x}_i^{n-1}) p(\mathbf{y}^n | \mathbf{x}^n)}{q(\boldsymbol{\xi}_i^n)} \left\| \frac{\partial \mathbf{x}^n}{\partial \boldsymbol{\xi}_i^n} \right\|$$

$$= \frac{1}{N_e} \frac{p(\mathbf{x}^n | \mathbf{x}_i^{n-1}, \mathbf{y}^n) p(\mathbf{y}^n | \mathbf{x}_i^{n-1})}{q(\boldsymbol{\xi}_i^n)} \left\| \frac{\partial \mathbf{x}^n}{\partial \boldsymbol{\xi}_i^n} \right\|,$$
(7)

where it is assumed that $w_i^{n-1} = 1/N_e$ for all particles *i*. To have equal weights $w_1^n = w_2^n = \ldots = w_{N_e}^n = w_{\text{target}}^n$ the unnormalized log-weights must also be equal, hence for each particle *i* the scalar α_i must satisfy

$$(\alpha_i - 1)\boldsymbol{\xi}_i^T \boldsymbol{\xi}_i - 2\log(\alpha_i^{N_x/2}) - 2\log\left(\left|1 + \frac{\partial \alpha_i^{1/2}}{\partial \boldsymbol{\xi}_i} \frac{\boldsymbol{\xi}_i}{\alpha_i^{1/2}}\right|\right) = C - \varphi_i, \quad (8)$$

 $_{214}$ for a constant C and with

$$\varphi_i = [\mathbf{y}^n - \mathbf{H}\mathcal{M}(\mathbf{x}_i^{n-1})]^T (\mathbf{R} + \mathbf{H}\mathbf{Q}\mathbf{H}^T)^{-1} [\mathbf{y}^n - \mathbf{H}\mathcal{M}(\mathbf{x}_i^{n-1})], \qquad (9)$$

215 so that

$$p(\mathbf{y}^n | \mathbf{x}_i^{n-1}) \propto e^{-\varphi_i/2}.$$
 (10)

In practice the scale factor α_i is determined numerically by solving

$$\gamma\left(\frac{N_x}{2}, \frac{\alpha_i \boldsymbol{\xi}_i^{n,T} \boldsymbol{\xi}_i^n}{2}\right) = e^{-c_i/2} \gamma\left(\frac{N_x}{2}, \frac{\boldsymbol{\xi}_i^{n,T} \boldsymbol{\xi}_i^n}{2}\right),\tag{11}$$

for α_i , where $\gamma(s, x) = \int_0^x t^{s-1} e^{-t} dt$ is the lower incomplete gamma function. 217 and we refer to $c_i = \max_j [\varphi_j] - \varphi_i$ as the *i*th offset. See Appendix for details. 218 By using the solution of (11) in the update expression (6) one ensures that 219 the unnormalized weight associated with the *i*th updated state vector \mathbf{x}_i^n is equal 220 to the chosen target weight. The log-weight offsets $c_1, c_2, \ldots, c_{N_e}$ are necessary 221 because the likelihood $p(\mathbf{y}^n|\mathbf{x}_i^{n-1}) \propto \exp(-\varphi_i/2)$ of the current observation 222 given the previous state of the *i*th particle will differ between particles. For 223 every particle i to reach the target weight we need $c_i \ge 0$. That is, the target 224 unnormalized weight cannot be set larger than the smallest unnormalized weight 225 in the ensemble. Consequently, since the incomplete γ -function is monotonically 226 increasing, we must have $\alpha_i \leq 1$ for every particle *i*. We therefore expect an 227 updated IEWPF ensemble to have a smaller spread than a sample drawn from 228 the OPD, and this suggests an explanation for the bias in the original IEWPF. 229 The offset c_i in equation (11) is chosen by targeting the smallest unnormalized 230

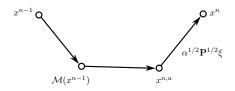

Figure 1: Single-stage IEWPF proposal scheme.

weight in the forecast ensemble. In principle, c_i could be defined differently, targeting for instance the average or median weight. Targeting the smallest weight, i.e. the maximum φ_i , has the advantage of making all offsets nonnegative, which guarantees that a solution of (11) exists.

In their original formulation of the IEWPF, Zhu et al. (2016) considered the 235 limiting case of (11) when $N_x \to \infty$. This yields a simplified equation for α_i 236 which admits an analytical solution in terms of the Lambert W function (Weis-237 stein, 2002). A feature of this closed-form solution is a gap between branches 238 of the Lambert W function, leaving a region in state space where the proposal 239 density of the filter is zero. The authors used both branches of the solution, one 240 corresponding to $\alpha_i \leq 1$ and one to $\alpha_i \geq 1$, to reduce the bias of the resulting 241 filter. We see here that using both solutions is in fact inconsistent, and only 242 the $\alpha_i \leq 1$ solutions are valid. In this article we do not simplify or approximate 243 equation (11). Instead we resort to numerical solution methods for determin-244 ing α_i . Although the solutions of (11) obtained in this way do not have a gap 245 between distinct branches, the resulting transformation from $\boldsymbol{\xi}_i^n$ to \mathbf{x}_i^n is not in 246 general bijective (see Section 2.3). 247

An elementary sketch of the particle movement of the single-stage IEWPF is summarized in Figure 1. Details of the IEWPF implementation are provided in the Appendix.

251 2.3 Properties of the single-stage IEWPF

The implicit formulation of the IEWPF makes it difficult to study the properties 252 of the resulting particle representation. For instance it is not clear, even in sim-253 plified model settings, how to calculate closed form expressions describing how 254 the IEWPF update changes the ensemble mean or variance. In what follows we 255 will nevertheless gain insight in the solutions via the form of the implicit trans-256 formation, and by simulating from a Gaussian model where the exact solution 257 is known. In Section 3 we then modify the algorithm and overcome some of the 258 shortcomings of the single-stage IEWPF. 259

Figure 2 shows solutions of the equal weights equation (11) for seven different 260 offsets c (ignoring the subscript *i* in this display). When implementing the 261 IEWPF, we require c > 0, but here we consider the more general case $c \in \mathbb{R}$. 262 The solutions in Figure 2 are shown in terms of the transformation from $\boldsymbol{\xi}$ to 263 $\alpha^{1/2}\boldsymbol{\xi}$. When c = 0 the solution is $\alpha = 1$ which gives the identity transformation. 264 Furthermore the solution α decreases with increasing c, so for c < 0 the resulting 265 transformation has the effect of expanding the probability distribution of the 266 perturbation $\boldsymbol{\xi}$, whereas for c > 0 the transformation contracts the distribution. 267 As can be seen in Figure 2 the contracting solutions for c > 0 have horizontal 268 asymptotes while the expanding solutions for c < 0 have vertical asymptotes. 269 As a consequence, the transformation from $\boldsymbol{\xi}$ to $\alpha^{1/2}\boldsymbol{\xi}$, and hence to \mathbf{x}^n , is not 270 defined on the whole domain when c > 0, and is not surjective when c < 0. Only 271 when c = 0 is the transformation bijective. When solving (11) with negative 272 offsets therefore, we are not free to use any proposal distribution for $\boldsymbol{\xi}$ as the 273 range of possible perturbation vectors must be restricted to the appropriate 274 subset of the domain. One could try to achieve this by truncating the proposal 275 distribution at the location of the vertical asymptote when c < 0. But this 276 is not a viable modification of the IEWPF, because truncation introduces a 277

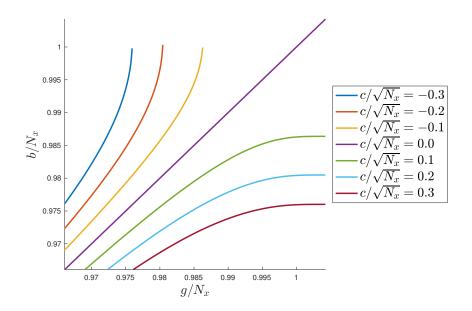

Figure 2: Solutions of (11) for different offsets c shown in terms of $g = \|\boldsymbol{\xi}\|$ and $b = \|\alpha^{1/2}\boldsymbol{\xi}\|$.

particle-dependent normalisation constant into the expression for the particle weights, making them unequal. Here, the requirement that weights be kept equal appears to be in conflict with the requirement that the transformation from $\boldsymbol{\xi}$ to \mathbf{x}^n should be a bijection from \mathbb{R}^{N_x} to \mathbb{R}^{N_x} (Chorin et al., 2010). A theoretical justification of the IEWPF ultimately necessitates the resolution of this conflict, but it is unclear whether it can be resolved.

Considering the OPD and the update expression (6), it is clear that when $\alpha_i < 1$, the IEWPF produces updated particles with a smaller variance than the OPD PF, which is known to be unbiased. Hence we expect underestimation of variance as a consequence of using only contracting solutions of the equalweights equation. As is illustrated in the following simulation study, the IEWPF does indeed tend to underestimate the variability of the state vector in the long run. To make the presentation of the IEWPF more concrete before introducing the revised version, we now apply the IEWPF to a test case involving a Gausslinear model. We revisit the same test case in Section 3.2 after describing the revised IEWPF. A more detailed description of the test case is given in Section 4.1.

We consider a size 100 state vector with initial state $\mathbf{x}^0 \sim N(0, \mathbf{B})$. The transition mechanism is defined by $\mathbf{x}^n \sim N(\mathbf{x}^{n-1}, \mathbf{Q})$, $n = 1, \ldots$ Further, observations are given by $\mathbf{y}^n \sim N(\mathbf{x}^n, \mathbf{R})$. The filtering distribution is then Gaussian and its mean and covariance matrix are provided by the Kalman filter (Kalman, 1960). The covariance matrices \mathbf{B} , \mathbf{Q} and \mathbf{R} are all diagonal, with constant diagonal entries of 1.0, 0.04 and 0.12 respectively.

When applying the IEWPF as defined by equation (6) and (8) to this model we find that while the ensemble mean matches the KF mean on average, the ensemble spread is too small to match the KF variance in the long run. This means that the IEWPF systematically underestimates the variance of the state (see Figures 3 and 4).

In Figure 3 the results of 1000 independent simulations are visualised for one 307 state variable (component 42) at time n = 120. We show the rank histogram of 308 the true variable in the set of $N_e = 25$ particles. This is computed by sorting 309 the particles from smallest to largest by the value of this component, and then 310 determining the position of the true value in this ordering. The procedure is 311 repeated for each simulation. When the true state is unavailable the preferred 312 approach is to carry out ranking in data space, comparing observations with 313 realizations of their model equivalents generated from the ensemble. For a 314 detailed treatment of rank histograms, their use and cautions, see Hamill (2001). 315 The rank of the true state relative to the ensemble should ideally be uniform, 316 but in Figure 3 we notice few ranks in the middle. The true value is too often 317

at the extremes of the distribution represented by the 25 particle members. 318 This means that the ensemble is underdispersive, i.e. the variability in the 319 particle set is too small. Figure 4 shows the distribution over 1000 simulations 320 of variance at time n = 20, averaged over all 100 entries of the state vector. 321 A corresponding variance distribution for the stochastic EnKF is included for 322 comparison. None of the filters being compared use inflation or localization. 323 The purpose of the comparison is not to show which filter performs better, 324 but rather to demonstrate that the IEWPF systematically underestimates the 325 filtering variance. The variance in the particle representation varies somewhat 326 between the different state vector entries but is mostly between 0.02 and 0.04. 327 In comparison, the variance calculated by the Kalman filter is 0.052 for all state 328 vector entries. Both the IEWPF and the EnKF underestimate the long-run 329 process variability for this example. For the EnKF, variance estimates become 330 more consistent with the KF level when the ensemble size is increased (Figure 331 4, bottom display). The same is not true of the IEWPF. 332

In Section 4 we provide further analysis of this example, studying how the filter behaves over time. We also compare results of the single-stage IEWPF with our new algorithm using two stages.

336 3 Modifying the IEWPF

To address the underestimation of variance by the IEWPF described in the previous section, we now introduce a modified version of the filter. We add a second perturbation vector η_i , orthogonal to $\boldsymbol{\xi}_i$, to the analysis state $\mathbf{x}_i^{n,a}$. We refer to the filter with two separate perturbation vectors as the two-stage IEWPF, while the original filter with one perturbation vector is referred to as the single-stage IEWPF. Like the single-stage filter, the two-stage case also involves a particle-specific parameter α_i which ensures equal particle weights.

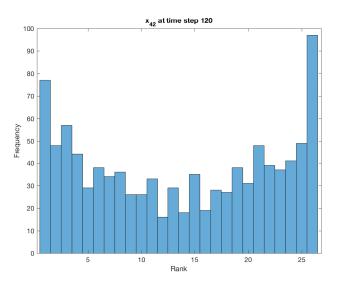

Figure 3: Rank histogram of x_{42}^{120} of true realisation relative to IEWPF ensemble over 1000 simulations. U-shape suggests ensemble is under-dispersed.

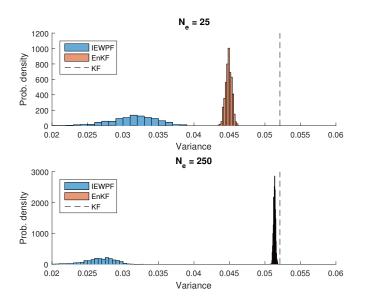

Figure 4: Histograms of estimates of Var(\mathbf{x}^{20}) from 1000 runs of the IEWPF and stochastic EnKF, averaged over $N_x = 100$ elements compared with deterministic KF result. **Top**: $N_e = 25$. **Bottom**: $N_e = 250$.

In the two-stage filter there is an additional parameter β , which is common to all particles and is related to the spread of the ensemble. Note that in the single-stage case, α_i depends on the unnormalised weight of the *i*th particle in the forecast ensemble as well as the magnitude of the sampled perturbation vector $\boldsymbol{\xi}_i$, i.e. $\alpha_{i,1\text{-stage}} = \alpha_i(\varphi_i, \|\boldsymbol{\xi}_i\|)$. In the two-stage case, α_i will also depend on β and the magnitude of $\boldsymbol{\eta}_i$, i.e. $\alpha_{i,2\text{-stage}} = \alpha_i(\varphi_i, \|\boldsymbol{\xi}_i\|, \beta, \|\boldsymbol{\eta}_i\|)$.

350 3.1 Two-stage IEWPF

In the two-stage proposal scheme, the updated particle \mathbf{x}_i^n is given by

$$\mathbf{x}_{i}^{n} = \mathbf{x}_{i}^{n,a} + \beta^{1/2} \mathbf{P}^{1/2} \boldsymbol{\eta}_{i} + \alpha_{i}^{1/2} \mathbf{P}^{1/2} \boldsymbol{\xi}_{i},$$
(12)

where the perturbation vectors $\boldsymbol{\xi}_i, \boldsymbol{\eta}_i \in \mathbb{R}^{N_x}$ are standard multivariate Gaussian random vectors satisfying $\boldsymbol{\xi}_i^T \boldsymbol{\eta}_i = 0$. Requiring orthogonality simplifies the particle weight expression so that the equal-weights equation for α_i has the same form as in the single-stage case. Using perturbation vectors that are not orthogonal would introduce extra terms in the equal-weights equation (see Appendix). The equal-weights equation for the updating scheme (12) is

$$(\alpha_i - 1)\boldsymbol{\xi}_i^T \boldsymbol{\xi}_i - 2\log(\alpha_i^{N_x/2}) - 2\log\left(\left|1 + \frac{\partial \alpha_i^{1/2}}{\partial \boldsymbol{\xi}_i} \frac{\boldsymbol{\xi}_i}{\alpha_i^{1/2}}\right|\right)$$

= $C - \varphi_i - (\beta - 1)\boldsymbol{\eta}_i^T \boldsymbol{\eta}_i.$ (13)

Note that (13) is identical to the single-stage equal-weights equation (8) with the offset now defined as $c_i = \max_j [D_j] - D_i$ where $D_j = \varphi_j - (1 - \beta) \eta_j^T \eta_j$.

The purpose of the additional perturbation η_i and the common scale factor β is to control the spread of the updated particles so that the filter correctly represents the variability of the filtered state. In applications β would be considered a tuning parameter.

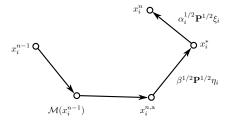

Figure 5: Two-stage IEWPF proposal scheme. Compare with Figure 1.

To determine a suitable value of β , particle ranks or coverage probabilities 358 may be used. Since the spread of the updated ensemble is sensitive to the value 359 of β , different values will produce differently shaped rank distributions and dif-360 ferent observed coverage probabilities. This can indicate whether the currently 361 used value of β is suitable and, if it is not, whether the value should be ad-362 justed up or down. An automated search procedure based on some quantitative 363 mismatch criterion—say, the difference between observed and nominal coverage 36 probabilities—is also possible. 365

A coverage probability is the observed frequency with which a prediction 366 interval covers the predicted quantity. Ideally it should match the interval's 367 nominal confidence level. For instance, an 80% prediction interval for y^n is 368 $(y_{(0,1N_e)}^n, y_{(0,9N_e)}^n)$, and on average about 80% of the data vector entries at time 369 n should fall within this interval. We suggest tuning β such that the coverage 370 probabilities at the 50%, 60%, ..., 90% levels all match their respective nominal 371 confidence level reasonably well. This entails running the algorithm for a range 372 of β values, and choosing a value that gives an acceptable calibration (see Section 373 4 for more details about how this is tuned in practical experiments). 374

An elementary sketch of the particle movement of the two-stage IEWPF is summarized in Figure 5. Implementation details are provided in the Appendix.

377 3.2 Properties of the two-stage IEWPF

As for the single-stage IEWPF, it is difficult to study analytical properties of the two-stage IEWPF, even in simplified model settings. Some insight can still be gleaned by simulating from a Gaussian model where the exact solution is known.

In section 2.3 we stated that the single-stage transformation from $\boldsymbol{\xi}$ to \mathbf{x} 382 implied by (6) is only injective for $c \ge 0$ and is only surjective for $c \le 0$, i.e. it 383 is a bijection only when c = 0. In the two-stage case we can think of the map 384 from $\boldsymbol{\xi}$ to \mathbf{x} as depending on $\boldsymbol{\eta}$ and $\boldsymbol{\beta}$ through c. That is, there is not one map 385 $\psi : \boldsymbol{\xi} \mapsto \mathbf{x}$, but a set $\{\psi_c : c \ge 0\}$ of maps where c is a function of β and $\boldsymbol{\eta}$. The 386 two-stage IEWPF keeps β fixed and draws a random η , thereby selecting one 387 of the maps ψ_c . Then $\boldsymbol{\xi}$ is drawn subject to the orthogonality constraint. For 388 any point $\mathbf{x} \in \mathbb{R}^{N_x}$ and any $c \ge 0$, there is some combination of $\boldsymbol{\eta}$ and $\boldsymbol{\xi}$ with 389 $\boldsymbol{\eta}^T \boldsymbol{\xi} = 0$ such that ψ_c maps $\boldsymbol{\xi}$ onto \mathbf{x} . With $\boldsymbol{\eta}$ fixed, there may not exist a $\boldsymbol{\xi}$ that 390 is orthogonal to η and is mapped onto **x**. Introducing a second perturbation 391 vector to randomize the selection of a map is thus a way to ensure that state 392 space is covered by the proposal distribution. 393

Since the proposal distribution of the additional perturbation vector is zeromean, the expectation of the state vector is the same under the two-stage update scheme as under the single-stage scheme. Hence, the modification does not induce a bias in the ensemble mean.

We return now to the Gauss-linear model from Section 2.3. A more detailed description of the test case is given Section 4.1. This time we apply the twostage IEWPF to the Gauss-linear test case. Results of this method and that of the Kalman filter are shown in Figures 6 and 7. As in Section 2.3, these are the results of 1000 independent simulations, and the results are presented for time n = 120. Also as in Section 2.3, the ensemble size is $N_e = 25$. Figure 6 shows the rank histograms for the true value of state vector entry 405 42. The rank histogram for $\beta = 0.05$ is clearly U-shaped. As β increases to 406 0.25 and 0.30 the rank distribution becomes more uniform. The rank histogram 407 for $\beta = 0.5$ is indistinguishable from a uniform distribution given the sampling 408 error and the calibration is better than when using the single-stage approach as 409 shown in Figure 3.

Figure 7 shows the distributions of average variances produced by the two-410 stage IEWPF for β set to 0.05, 0.25, 0.30 and 0.50. The average is taken over all 411 elements of the state vector. The display also shows the Kalman filter variance 412 estimate as a thin, vertical line. Ideally the IEWPF should produce an ensemble 413 whose variance matches the KF variance. Of the four β -values considered, 414 0.3 and 0.5 come closest to realizing this, showing a clear improvement over 415 the variance distribution of the single-stage IEWPF in Figure 4. Judging by 416 Figure 7, the optimal value of β in terms of variance calibration seems to lie 417 closer to 0.3 than to 0.5 in this case. Yet Figure 6 shows a more uniform 418 rank distribution for $\beta = 0.5$ than for $\beta = 0.3$. It is important to keep in 419 mind, however, that comparing the rank histograms in terms of their degree of 420 departure from uniformity is less precise than comparing the more concentrated 421 variance histograms in terms of their locations along the horizontal axis. Figure 422 7 is therefore probably a better guide to identifying the optimal value of β . 423 On the other hand, it cannot be ruled out that the discrepancy between the 424 two figures has a different cause, such as the updated particles having a non-425 Gaussian distribution. 426

427 4 Numerical experiments

We present two synthetic test cases for assessing the performance of the IEWPF algorithms described in sections 2 and 3. The first is a Gauss-linear test case

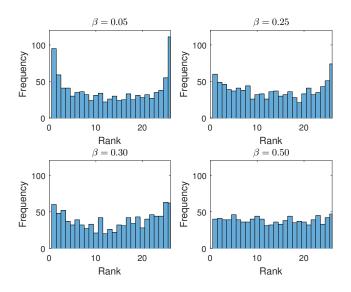

Figure 6: Rank histogram of x_{42}^{120} of true realisation relative to IEWPF ensemble over 1000 simulations. Results are for the two-stage IEWPF using four different values of β .

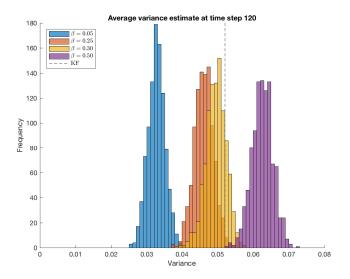

Figure 7: Histograms of two-stage IEWPF estimates of the variance of \mathbf{x}^{120} , averaged over all elements, for four different values of β , based on 1000 simulations each.

where the dynamical system evolves according to a linear model and the system 430 state is observed directly except for an additive observation error term. In the 431 second case the state evolves according to the Lorenz96 model (Lorenz, 1995) 432 and we observe every second element of the state vector. We assume Gaussian 433 probability distributions for the initial state, model errors and observation errors 434 as described in section 2.1. In the Gauss-linear case the filtering distribution 435 is analytically available via the Kalman filter under these assumptions, and we 436 will make use of this to judge the quality of the estimates produced by the 437 single-stage and two-stage IEWPFs. 438

439 4.1 Gauss-linear model

This is the Gauss-linear test case referred to in Sections 2.3 and 3.2. We re-use the model and observation equations from Section 3.1 of Zhu et al. (2016):

$$\mathbf{x}^n = \mathbf{x}^{n-1} + \mathbf{u}^n,\tag{14}$$

$$\mathbf{y}^n = \mathbf{x}^n + \mathbf{v}^n,\tag{15}$$

$$\mathbf{u}^n \sim N(0, \mathbf{Q}), \quad \mathbf{v}^n \sim N(0, \mathbf{R}), \quad \mathbf{x}^0 \sim N(0, \mathbf{B}),$$

 $N_x = 100,$ $n_t = 120,$ $\mathbf{Q} = 0.04\mathbf{I},$ $\mathbf{R} = 0.12\mathbf{I},$ $\mathbf{B} = \mathbf{I}.$

The filtering probability density $p(\mathbf{x}^n | \mathbf{y}^1, \dots, \mathbf{y}^n)$ is Gaussian with parame-

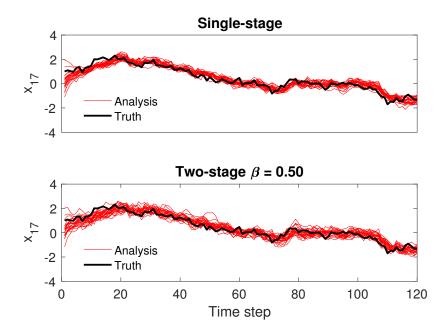

Figure 8: Example trajectories of x_{17} under Gauss-linear model. **Top**: Single stage IEWPF. **Bottom**: Two-stage IEWPF with $\beta = 0.5$. In both panels analysis ensemble members are shown in red and the true model trajectory in black.

ters μ^n and \mathbf{P}^n , given recursively via the Kalman filter:

$$\mu^{n} = \mu^{n-1} + (\mathbf{P}^{n-1} + \mathbf{Q})(\mathbf{R} + \mathbf{P}^{n-1} + \mathbf{Q})^{-1}(\mathbf{y}^{n} - \mu^{n-1})$$
$$\mathbf{P}^{n} = \mathbf{P}^{n-1} + \mathbf{Q} - (\mathbf{P}^{n-1} + \mathbf{Q})(\mathbf{R} + \mathbf{P}^{n-1} + \mathbf{Q})^{-1}(\mathbf{P}^{n-1} + \mathbf{Q}),$$
(16)

440 where $\mu^0 = \mathbf{0}$ and $\mathbf{P}^0 = \mathbf{B}$.

We compare results of the single-stage and two-stage IEWPF, using the KF filtering distribution (16) as a reference solution. The number of particles is $N_e = 25$, and we run the algorithm for 1000 simulations.

Example trajectories of the single-stage and two-stage IEWPF algorithms are shown in Figure 8. Both follow the true state pretty well, but the single-stage results (top display) have less variability.

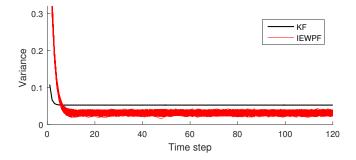

Figure 9: Comparison of posterior variance estimates from the Kalman filter and the single-stage IEWPF for state vector entry 42 in the Gaussian linear model case with $N_x = 100$ and $N_e = 25$. The IEWPF variance curves show the result of 1000 repetitions of the filtering task.

Figure 9 shows variance results for the single-stage IEWPF over the assimilation steps. Initial filtering variance, specified through the background error covariance matrix **B**, is 1. The variance of the KF filtering distribution decreases quickly before stabilising, while the IEWPF ensemble variance takes longer to stabilise, and does so at a lower variance level. Comparing the IEWPF and KF variance estimates, it is clear that the IEWPF overestimates the filtering variance early on, and underestimates it in the long run.

Figure 10 shows average two-stage IEWPF variance estimates over the assimilation steps. As in the single-stage case (Figure 9), variability is still overestimated at the beginning of the time interval, but the long-run KF variance can now be matched quite well by an appropriate choice of β .

458 4.2 Lorenz96 model

⁴⁵⁹ We study the performance of the single and two-stage IEWPF using the model ⁴⁶⁰ presented in Section 3.2 of Zhu et al. (2016). The dynamical model is given by

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = -x_{i-2}x_{i-1} + x_{i-1}x_{i+1} - x_i + F, \qquad i = 1, \dots, N_x, \tag{17}$$

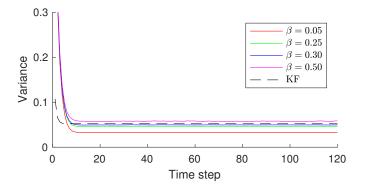

Figure 10: Evolution of variance estimates from the two-stage IEWPF with four different values of the common scale factor β . The solid curves show variance estimates averaged over 1000 independent simulations. The Kalman filter variance estimate is included for comparison.

where the indices wrap around so that x_{N_x+1} is identified with x_1 . Letting $\mathbf{x}^n = \mathbf{x}(t_n)$ with $t_n = n\Delta t$, the model equation can be written as

$$\mathbf{x}^n = \mathcal{M}(x^{n-1}) + \mathbf{u}^n, \qquad \mathbf{u}^n \sim N(0, \mathbf{Q}), \qquad n = 1, \dots, n_t,$$

where \mathcal{M} denotes integration of equation (17) by a fourth order Runge-Kutta scheme and

$$N_x = 40, \qquad n_t = 300, \qquad F = 8, \qquad \Delta t = 0.05.$$

Observations are gathered at every time step t_n , $n = 1, ..., n_t$, which means that here Δt is both the integration time step of the numerical solution of (17) and the time between successive observation time points. Data are related to the state vector by

$$\mathbf{y}^n = \mathbf{H}\mathbf{x}^n + \mathbf{v}^n, \qquad \mathbf{v}^n \sim N(0, \mathbf{R}),$$

where **H** is a selection matrix which picks out every second element of the state vector, so that $\mathbf{H}\mathbf{x}^n = (x_2^n, x_4^n, \dots, x_{N_x}^n)^T$. The remaining model parameters are specified as follows:

$$\mathbf{B} = \text{tridiag}(0.25, 1, 0.25), \quad \mathbf{Q} = \text{tridiag}(0.025, 0.10, 0.025), \quad \mathbf{R} = 0.16I_{2}$$

where tridiag (a_1, a_2, a_3) is a tridiagonal matrix with a_1 in every entry of the first subdiagonal, a_2 on the main diagonal and a_3 on the first superdiagonal. The nonlinearity in this data assimilation test case is weak due to the high frequency of observations. Increasing the time between updates would give a more severe test of the filter. A weakly nonlinear test case is still suitable for demonstrating that the IEWPF ensemble spread can be controlled through the choice of β .

We run the single-stage and two-stage IEWPF variants on this test case, 478 with $N_e = 100$ in both cases. Figure 11 shows results of the two-stage IEWPF 479 using $\beta = 0.7$, where we plot the filtering distribution over time along with the 480 truth. This is done for two entries of the state vector (component 1 and 2). The 481 ensemble tracks the reference state and covers the truth reasonably well. The 482 bottom display shows the estimated variances of component 1 and 2. Because 483 the observations provide much more information about the second entry, this 484 has smaller variance over time. 485

In Figure 12 we plot coverage probabilities at one time step. These are 486 plotted for different β parameters and for different confidence levels. The tuning 487 procedure tells us that a value of β near 1 is useful in this example because it 488 gives the best predictive performance, and any value in the range 0.7 - 1.2489 would be acceptable. Figure 13 compares rank histograms of one run each of 490 the single-stage IEWPF and the two-stage IEWPF with $\beta = 0.7$, the latter 491 being the same run used to make Figure 11. The single-stage rank histogram 492 has a clear U-shape while the two-stage rank histogram does not, suggesting 493

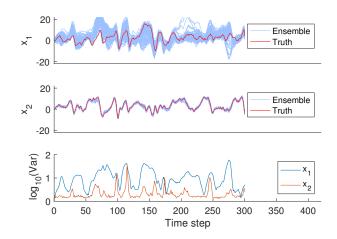

Figure 11: Time evolution of true realisations and an IEWPF ensemble. The components shown are x_1 (not directly observed) and x_2 (directly observed) along with ensemble variances. This ensemble was obtained from the two-stage IEWPF with $\beta = 0.7$ applied to the standard Lorenz96 case with $N_x = 40$.

⁴⁹⁴ that the two-stage IEWPF is better calibrated.

Finally, to test the two-stage IEWPF in a setting that is both weakly non-495 linear and where N_x is much larger than N_e , we run the Lorenz96 case with 496 $N_x = 1000, N_e = 25$ and $\beta = 0.75$. Remaining parameter values are unchanged. 497 Figure 14 shows two components of the estimated and true model trajectories in 498 this moderately high-dimensional test case. The top and bottom displays show 499 particle trajectories for an observed component and an unobserved component 500 of the state vector respectively. Filter behaviour is not noticeably different from 501 the lower dimensional case of Figure 11. The variance is clearly larger for the 502 unobserved state. For both variables, coverage is reasonable, and no bias effects 503 are apparent. As is common in Lorenz models, the state is sometimes very un-504 certain; for instance at time steps 120–150, and especially so for the unobserved 505 state. Even though the state dimension is much larger here, it seems that β 506 can be in the same range ($\beta = 0.75$ in this plot as opposed to $\beta = 0.7$ in the 507 $N_x = 40$ case). 508

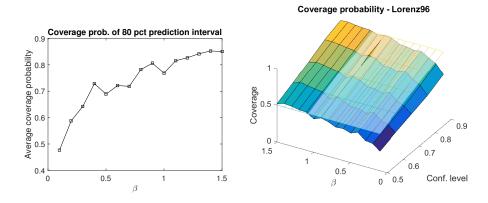

Figure 12: Empirical coverage probability as a function of prediction interval confidence and the value of the tuning parameter β . Best calibration is achieved for $\beta \approx 1$. Left: Average empirical coverage probability of 80 per cent prediction intervals constructed from two-stage IEWPF ensembles with a range of β values. Right: Coverage probabilities as a function of β for a range of confidence levels.

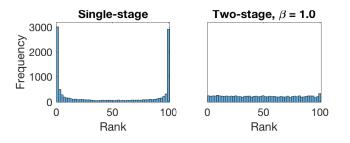

Figure 13: Rank histograms for one run of the single-stage IEWPF and one run of the two-stage IEWPF with $\beta = 0.7$ on the Lorenz96 model test case. Ranks are aggregated over all steady-state time steps and all state elements.

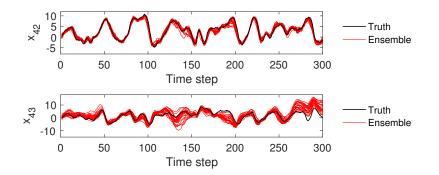

Figure 14: Two components of the trajectories of the ground truth and twostage IEWPF ensemble in the high-dimensional Lorenz96 case with $N_x = 1000$ and $N_e = 25$. The components shown are x_{42} (directly observed) and x_{43} (not directly observed). The common scale factor in the two-stage IEWPF was set to $\beta = 0.75$ in this case.

509 5 Conclusion

In this paper we have presented a modification to the Implicit Equal Weight Particle Filter (IEWPF). The suggested approach is applicable to data assimilation in both low and high-dimensional state space models. When applied to a weakly nonlinear dynamical model, the revised IEWPF performed reasonably well even in the $N_x \gg N_e$ case.

A MATLAB implementation of the IEWPF algorithm ran in seconds to min-515 utes when applied to the Gauss-linear and Lorenz96 data assimilation test cases 516 in Section 4. The runtime increases in proportion with the number of time 517 steps. It is not sensitive to the state dimension, but the numerical solution of 518 the equal-weights equation may require more iterations to achieve convergence 519 for very high-dimensional cases. The IEWPF update can be carried out in par-520 allel for each particle once the weight-offsets for the whole ensemble have been 521 determined, making the algorithm easy to parallelize. The memory require-522 ments of the IEWPF are largely determined by the need to store the model 523 error and observation error covariance matrices. 524

When using the revised filtering method, particles are updated according 525 to a two-stage proposal scheme which draws two separate and orthogonal per-526 turbation vectors from the proposal distribution. By using two stages, we are 527 able to eliminate the gap in the proposal distribution of the original IEWPF, 528 ensuring that the proposal distribution is nonzero everywhere in state space. 529 The random perturbations are scaled to keep weights equal and to achieve the 530 correct ensemble spread. Accurately adjusting the spread requires tuning of 531 the corresponding scale parameter. In our setting this is a single parameter 532 which we propose to specify through the use of coverage probabilities or rank 533 histograms. Other approaches might be possible here, for instance a criterion 534 guided by the distribution of weights in the optimal particle density proposal. 535 We leave this for future work. Note that we have chosen to keep the tuning 536 parameter fixed throughout the data assimilation period. One could also adjust 537 this parameter dynamically, so that different values can be used at different 538 assimilation times as is done in adaptive inflation for EnKFs. 539

The updating schemes described in this paper are constructed so that the distribution of particle weights will be uniform. An alternative would be to fix some proportion of the weights, allowing the rest to vary. This has the possible benefit of balancing contracting and expanding solutions of the equal-weights equation. Another possibility is to select multiple target weights, so that the overall distribution of weights is uniform within sub-ensembles of particles, but may differ between sub-ensembles.

605 Appendix

⁶⁰⁶ Single-stage IEWPF equal-weights equation

Suppose we have a forecast ensemble $\{\mathcal{M}(\mathbf{x}_{i}^{n-1})\}_{i=1}^{N_{e}}$ with equal weights at the previous time step, and we want to update this ensemble with respect to the observation \mathbf{y}^{n} . We sample the perturbation vector $\boldsymbol{\xi}_{i}^{n}$ from the proposal distribution $q(\boldsymbol{\xi}_{i}^{n})$. The updated weight of particle *i* is

$$w_i^n = \frac{p(\mathbf{x}_i^n | \mathbf{x}_i^{n-1}, \mathbf{y}^n) p(\mathbf{y}^n | \mathbf{x}_i^{n-1})}{q(\boldsymbol{\xi}_i^n)} \left\| \frac{\partial \mathbf{x}_i^n}{\partial \boldsymbol{\xi}_i^n} \right\|$$

 $_{611}$ Taking $-2\log$ of both sides gives

$$-2\log w_i^n = -2\log p(\mathbf{x}_i^n | \mathbf{x}_i^{n-1}, \mathbf{y}^n) - 2\log p(\mathbf{y}^n | \mathbf{x}_i^{n-1}) + 2\log q(\boldsymbol{\xi}_i^n) - 2\log \left(\left\| \frac{\partial \mathbf{x}_i^n}{\partial \boldsymbol{\xi}_i^n} \right\| \right)$$

and using that $p(\mathbf{x}_i^n | \mathbf{x}_i^{n-1}, \mathbf{y}^n) \propto \exp(-\frac{1}{2}(\mathbf{x}_i^n - \mathbf{x}_i^{n,a})^T \mathbf{P}^{-1}(\mathbf{x}_i^n - \mathbf{x}_i^{n,a}))$ and $p(\mathbf{y}^n | \mathbf{x}_i^{n-1}) \propto \exp(-\frac{1}{2}\varphi_i)$ this becomes

$$-2\log w_i^n = (\mathbf{x}_i^n - \mathbf{x}_i^{n,\mathrm{a}})^T \mathbf{P}^{-1} (\mathbf{x}_i^n - \mathbf{x}_i^{n,\mathrm{a}}) + \varphi_i - (\boldsymbol{\xi}_i^n)^T \boldsymbol{\xi}_i^n - 2\log\left(\left\|\frac{\partial \mathbf{x}_i^n}{\partial \boldsymbol{\xi}_i^n}\right\|\right)$$
$$= (\alpha_i - 1)(\boldsymbol{\xi}_i^n)^T \boldsymbol{\xi}_i^n + \varphi_i^n - 2\log\left(\left\|\frac{\partial \mathbf{x}_i^n}{\partial \boldsymbol{\xi}_i^n}\right\|\right)$$
$$= (\alpha_i - 1)(\boldsymbol{\xi}_i^n)^T \boldsymbol{\xi}_i^n + \varphi_i^n - 2N_x \log \alpha_i^{1/2}$$
$$- 2\log\left(\left|1 + \frac{\partial \alpha_i^{1/2}}{\partial \boldsymbol{\xi}_i^n} \frac{\boldsymbol{\xi}_i^n}{\alpha_i^{1/2}}\right|\right) - 2\log\left\|\mathbf{P}^{1/2}\right\|$$

where we have used the single-stage IEWPF update scheme (6) and rewritten the determinant of the Jacobian using Sylvester's determinant lemma (Brookes, 2011). Equating the negative log-weight with a constant *C* now gives

$$(\alpha_i - 1)(\boldsymbol{\xi}_i^n)^T \boldsymbol{\xi}_i^n + \varphi_i^n - 2N_x \log \alpha_i^{1/2} - 2\log \left(\left| 1 + \frac{\partial \alpha_i^{1/2}}{\partial \boldsymbol{\xi}_i^n} \frac{\boldsymbol{\xi}_i^n}{\alpha_i^{1/2}} \right| \right) - 2\log \left\| \mathbf{P}^{1/2} \right\| = C$$

615 OT

$$(\alpha_i - 1)(\boldsymbol{\xi}_i^n)^T \boldsymbol{\xi}_i^n - 2N_x \log \alpha_i^{1/2} - 2\log \left(\left| 1 + \frac{\partial \alpha_i^{1/2}}{\partial \boldsymbol{\xi}_i^n} \frac{\boldsymbol{\xi}_i^n}{\alpha_i^{1/2}} \right| \right) = c_i \qquad (18)$$

where $c_i = C - \varphi_i$ and $2 \log \|\mathbf{P}^{1/2}\|$ has been absorbed into C since it is the same for all particles. If it is assumed that α_i depends on $\boldsymbol{\xi}_i^n$ only through $g_i = (\boldsymbol{\xi}_i^n)^T \boldsymbol{\xi}_i^n$, then the above equation simplifies to

$$(\alpha_i - 1)g_i - 2\log\left(\alpha_i^{N_x/2 - 1}\frac{\partial \alpha_i g_i}{\partial g_i}\right) = c_i.$$

619 Writing $b_i = \alpha_i g_i$, this is

$$b_i - g_i + 2\log g_i^{N_x/2-1} - 2\log\left(b_i^{N_x/2-1} \left|\frac{\partial b_i}{\partial g_i}\right|\right) = c_i.$$

Separating the terms involving b_i and g_i gives

$$\log\left(\exp\left(\frac{b_i}{2}\right)b_i^{N_x/2} \left|\frac{\partial b_i}{\partial g_i}\right|\right) = \log\left(\exp\left(\frac{g_i}{2}\right)g_i^{N_x/2-1}\right) - \frac{c_i}{2}$$
$$\exp\left(-\frac{b_i}{2}\right)b_i^{N_x/2-1} \left|\frac{\partial b_i}{\partial g_i}\right| = \exp\left(-\frac{g_i}{2}\right)g_i^{N_x/2-1}\exp\left(-\frac{c_i}{2}\right)$$

which, when integrated from $g_i = 0$ to $g_i = \tilde{g}_i$, yields the single-stage equalweights equation (11).

⁶²² Two-stage IEWPF equal-weights equation

In the two-stage IEWPF we draw two orthogonal perturbation vectors $\boldsymbol{\xi}_{i}^{n}$ and $\boldsymbol{\eta}_{i}^{n}$ from the proposal distribution $q(\boldsymbol{\xi}_{i}^{n},\boldsymbol{\eta}_{i}^{n})$, and use them to compute the updated particle position according to the two-stage update scheme (12).

⁶²⁶ Orthogonal pairs of multivariate normal perturbation vectors are generated ⁶²⁷ as follows:

1. Generate η and z by sampling from the standard N_x -variate Gaussian distribution.

⁶³⁰ 2. Decompose \mathbf{z} into two components $\mathbf{z} = \mathbf{z}_{\parallel} + \mathbf{z}_{\perp}$ where \mathbf{z}_{\parallel} is parallel to $\boldsymbol{\eta}$ ⁶³¹ and \mathbf{z}_{\perp} is orthogonal to $\boldsymbol{\eta}$.

3. Let
$$\boldsymbol{\xi} = \sqrt{(\mathbf{z}^T \mathbf{z})/(\mathbf{z}_{\perp}^T \mathbf{z}_{\perp})} \mathbf{z}_{\perp}$$
, so that $\boldsymbol{\xi}^T \boldsymbol{\xi} = \mathbf{z}^T \mathbf{z}_{\perp}$

For a pair $\boldsymbol{\xi}, \boldsymbol{\eta} \in \mathbb{R}^{N_x}$ satisfying $\boldsymbol{\xi}^T \boldsymbol{\eta} = 0$, we have

$$q(\boldsymbol{\xi},\boldsymbol{\eta}) \propto \exp\left(-\frac{1}{2}\boldsymbol{\eta}^{T}\boldsymbol{\eta}\right) \exp\left(-\frac{1}{2}\boldsymbol{\xi}^{T}\boldsymbol{\xi}\right) I(\boldsymbol{\xi}^{T}\boldsymbol{\eta}=0),$$
(19)

where $I(\boldsymbol{\xi}^T \boldsymbol{\eta} = 0)$ is an indicator function that is equal to one if $\boldsymbol{\xi}^T \boldsymbol{\eta} = 0$ and is equal to zero if $\boldsymbol{\xi}^T \boldsymbol{\eta} \neq 0$.

⁶³⁶ Under the two-stage scheme, assuming that since β is shared between parti-⁶³⁷ cles the Jacobian matrix of the map from η_i^n to \mathbf{x}_i^n can be omitted, the expression $_{638}$ for the weight of particle *i* is

$$w_i^n = \frac{p(\mathbf{x}_i^n | \mathbf{x}_i^{n-1}, \mathbf{y}^n) p(\mathbf{y}^n | \mathbf{x}_i^{n-1})}{q(\boldsymbol{\xi}_i^n, \boldsymbol{\eta}_i^n)} \left\| \frac{\partial \mathbf{x}_i^n}{\partial \boldsymbol{\xi}_i^n} \right\|$$

and taking $-2\log$ and proceeding as in the single-stage case now gives

$$(\alpha_i - 1)(\boldsymbol{\xi}_i^n)^T \boldsymbol{\xi}_i^n + (\beta - 1)(\boldsymbol{\eta}_i^n)^T \boldsymbol{\eta}_i^n + \varphi_i^n - 2N_x \log \alpha_i^{1/2} - 2\log\left(\left|1 + \frac{\partial \alpha_i^{1/2}}{\partial \boldsymbol{\xi}_i^n} \frac{\boldsymbol{\xi}_i^n}{\alpha_i^{1/2}}\right|\right) - 2\log\left\|\mathbf{P}^{1/2}\right\| = C$$

639 and

$$(\alpha_i - 1)(\boldsymbol{\xi}_i^n)^T \boldsymbol{\xi}_i^n - 2N_x \log \alpha_i^{1/2} - 2\log \left(\left| 1 + \frac{\partial \alpha_i^{1/2}}{\partial \boldsymbol{\xi}_i^n} \frac{\boldsymbol{\xi}_i^n}{\alpha_i^{1/2}} \right| \right) = C - \varphi_i - (\beta - 1)(\boldsymbol{\eta}_i^n)^T \boldsymbol{\eta}_i^n$$

 $_{640}$ which matches equation (18) if we let

$$c_i = C - \varphi_i - (\beta - 1)(\boldsymbol{\eta}_i^n)^T \boldsymbol{\eta}_i^n = C + (1 - \beta)(\boldsymbol{\eta}_i^n)^T \boldsymbol{\eta}_i^n - \varphi_i.$$
(20)

⁶⁴¹ Consequently α_i can be determined in the two-stage case by solving equation ⁶⁴² (11) with offset c_i given by (20).
