Declaration of conflict of interest: none

1 Highlights

- 2 D-allulose did not retard the onset of starch gelatinisation as effectively as sucrose did.
- 3 Weight loss during baking was slower for D-allulose cupcakes.
- 4 Textures of D-allulose and sucrose cupcakes were comparable at the longest baking time.
- 5 D-allulose and D-fructose produced cupcakes of similar physical properties.

7 Abstract

The high sucrose content in sweet bakery products is a nutritional concern. However, the 8 technological functions of sucrose in such products make its replacement challenging. D-9 10 allulose, which only has 5% of the energy content of sucrose, may be an ideal sucrose substitute, due to its similar physicochemical and bulk properties. The aim of this study was 11 12 to investigate the performance of D-allulose as the main sugar component in cupcakes, in 13 comparison to both sucrose and D-fructose, by assessing the physicochemical and physical properties of cupcakes baked for 12, 16, and 20 min. D-allulose batters experienced less 14 15 volume expansion and took longer to lose weight and thermally set during baking than did sucrose batters. D-allulose cupcakes had lower water activity values at all baking times and 16 17 developed a browner colour and greater acrylamide concentration, compared to sucrose 18 cupcakes. Comparable textural properties were achieved by D-allulose and sucrose cupcakes 19 at the longest baking time (20 min). D-allulose and D-fructose produced cupcakes with comparable physical properties. There is potential for the use of D-allulose in the bakery 20 21 products industry, by employing longer baking processes, or in other products requiring lower moisture content and less volume development. 22

23 Keywords:

24 D-allulose, sucrose, D-fructose, sugar replacement, cupcake

26 **1. Introduction**

27 Sucrose is a non-reducing disaccharide used worldwide, and this sugar is a principal 28 ingredient of many food products. However, due to the high energy content of sucrose (4 kcal/g), a high intake of this sugar leads to excessive energy consumption. This has been 29 found to be a risk factor for obesity, which has been linked to chronic noncommunicable 30 diseases such as type 2 diabetes and cardiovascular disease. Dietary recommendations by 31 governments and health organisations around the world suggest to limit free sugar intake, 32 33 from disaccharides (e.g. sucrose) and monosaccharides (e.g. fructose and glucose), which are 34 widely added to foods, to no more than 10% to 5% of total daily energy intake SACN (2015); (WHO, 2015). Consequently, the food industry is being pressured to reformulate products 35 36 containing high free sugars to address these recommendations. D-allulose, also known as D-psicose, is a ketohexose monosaccharide and the C-3 37 38 epimer of D-fructose. It has a sweetness equivalent to 70% of that of sucrose, but is classed as an ultra-low-calorie sugar because it has an available energy content of just 0.2 kcal/g, 39 meaning it only has 5% of the energy of sucrose or D-fructose (Lamothe et al., 2019). D-40 allulose also has almost no effect on blood glucose levels, due to its negligible glycaemic 41 42 index, unlike those of sucrose and D-fructose (Lamothe et al., 2019; Pocan, Ilhan, & Oztop, 2019). Therefore, D-allulose is suitable for consumption by diabetic patients, making it a 43 44 potentially ideal substitute for sucrose and a better option compared to other free sugars 45 (such as D-fructose), from a nutritional point of view. D-allulose exists in nature only in small quantities and in residue of fermented molasses (Belitz, Grosch, & Schieberle, 2004). 46 However, mass production of D-allulose has become feasible. The introduction of a new 47 technique utilising immobilised enzymes means that D-allulose can be produced from D-48 49 fructose by the action of D-tagatose 3-epimerase in a simple yet cost effective method

(Granström, Takata, Tokuda, & Izumori, 2004). The US Food and Drug Administration (FDA)
approved D-allulose to be 'generally recognised as safe'(GRAS) (Zhang, Zhang, Jiang, & Mu,
2017). D-allulose is exempted from "Sugars" and "Added Sugars" labelling; and it is now
available in a non-GM crystalline form as DOLCIA PRIMA® Crystalline Allulose from Tate &
Lyle (Tate & Lyle, 2021).Directional prices in the US market for sucrose, allulose and fructose
are \$0.94/kg, \$3.42/kg and \$1.10/kg respectively.

56 Cakes, cake bars, and other sweet baked goods such as cookies are high-sugar products relished by consumers. Sucrose is the most commonly used sugar in cake making 57 (Struck, Jaros, Brennan, & Rohm, 2014), and it has a variety of functions, besides simply 58 imparting sweetness (E. J. Lee, Moon, & Kweon, 2020; Slade, Kweon, & Levine, 2021). During 59 batter preparation, sucrose helps to form a stable foam-emulsion and minimise gluten 60 61 development, giving cake its tender texture (Slade et al., 2021; Wilderjans, Luyts, Brijs, & 62 Delcour, 2013) During baking, sucrose elevates phase transitions like starch gelatinisation, gluten and egg white protein thermosetting (Donovan, 1977; Slade & Levine, 1991; van der 63 Sman & Renzetti, 2020). At high temperatures during baking, sucrose inverts to its 64 65 constituent reducing sugars, D-glucose and D-fructose, which then take part in Maillard and caramelisation reactions, thus providing cake with a pleasant flavour and golden-brown 66 67 colour (Davis, 1995). Sucrose interacts with and holds water, lowering water activity which 68 limits microbiological activity and mould formation (Davis, 1995; Slade & Levine, 1991); delaying moisture migration during storage, and interacting with starch, thereby delaying 69 the onset of starch retrogradation (Slade et al., 2021; Slade & Levine, 1991), and thus 70 71 maintaining the moist and soft texture of cake for a longer time (Gélinas, Roy, & Guillet, 72 1999).

73 Despite sucrose's extensive list of complex functions, the physicochemical properties of D-allulose suggest that this sugar could be a promising substitute in sweet baked goods 74 such as cookies (Kweon, Slade, Levine, & Gannon, 2014; Young, S., & Kweon, 2016) and cake 75 76 products (E. J. Lee et al., 2020; Sun, Hayakawa, Ogawa, Fukada, & Izumori, 2008). D-allulose 77 has a high solubility in water, which makes its use in food processing easier, and it also 78 contributes a similar amount of bulk to foods as does sucrose, as well as having a clean taste, 79 smooth texture, and desirable mouthfeel (Sun et al., 2008). D-allulose has also been shown to have an ability to improve product quality and processing characteristics of various foods; 80 it enhanced brown colour development in cookies, as a result of accelerated Maillard 81 82 reactions, due to its reducing nature (Sun et al., 2008). It has also been shown to improve the foaming capacity (O'Charoen, Hayakawa, Matsumoto, & Ogawa, 2014) and gelling 83 84 behaviour (Sun, Hayakawa, & Izumori, 2004) of egg white proteins, as well as to improve the 85 textural properties of soft candies (Pocan et al., 2019). A study by P. Lee, Oh, Kim, and Kim (2020) concluded that 25% substitution of sucrose with D-allulose is likely to be appropriate 86 in pound cakes. Although it is worth considering sucrose replacement with D-allulose in 87 88 cakes and cookies, for nutritionally beneficial reasons, it is still not fully understood how this monosaccharide interacts in such sweet bakery matrices, and how it influences the 89 90 development of the final crumb structure. Understanding of these mechanisms is essential 91 to allow a more tailored use of D-allulose in such sweet bakery systems, to achieve optimal product physical properties. 92

The main aim of the present study was to investigate the performance of D-allulose as the main sugar component in cupcakes, in terms of its effect on the thermal setting mechanism of batter and the physical properties of cupcakes, compared to those of sucrose. To support this work, the relationship between ketohexose chemical structure and

97 technological functionality was investigated by also comparing the performance of Dfructose in the cupcake system. The influence these three sugars had on starch gelatinisation 98 was assessed using differential scanning calorimetry (DSC). All three sugars were then 99 100 incorporated into cupcake batter, and the resulting cupcakes' weight loss during baking, 101 height, cellular crumb structure, textural properties, colour, and acrylamide levels were each 102 analysed after 3 different baking times (12, 16, and 20 min). The results of this study should 103 provide essential findings for the development of recipes using D-allulose to produce 104 nutritionally improved sweet bakery products such as cakes and cookies that will as well 105 have optimal texture and volume. 106 2. Methods and Materials 2.1. Ingredients 107 108 The ingredients used in this study included the following: sucrose (Caster Sugar, Tate and 109 Lyle, London, UK), D-allulose (Sensato, Netrition Inc., Albany, NY), D-fructose (Danisco, Copenhagen, Denmark), wheat flour (British Plain Flour, protein content: 9.7%; , Sainsburys 110 Supermarkets Ltd, London, UK; specification details supplied by UK Flour Millers Association 111 112 for UK plain flour :moisture : 13.6 – 14.8 %; colour tristimulus (L*-b*): 77.0 min; Hagberg 113 Falling Number: 150 min; water absorption: 54.0 – 58.0%), margarine (Stork Original Spread, Stork UK and Ireland, London, UK), pasteurised free range whole eggs (West Horsley Dairy 114 115 Ltd, Woking, UK), baking powder (diphosphates and sodium carbonates)(Dr Oetker (UK) Ltd., 116 Leeds, UK), salt (NaCl), and distilled water (pH 5.38 (0.10)). Acrylamide (>99%) was purchased from Sigma-Aldrich (St Louis, MO). 1,2,3⁻¹³C3-Acrylamide (1000 mg/L in methanol) 117 118 was purchased from LGC Standards (Teddington, UK); 1 mL was diluted to 1 L in deionized

water to provide a 1 mg/L stock solution. Further details on the chemical properties of the
sugars used are presented in Table 1.

121 2.2. DSC of Wheat Flour and Sugar Solution Mixtures

122 DSC was used to analyse the thermal gelatinisation behaviour of the starch in wheat flour, in water and in the presence of the three different sugar solutions. A modified version of the 123 method described by Kweon, Slade, and Levine (2016) was followed. Equal mass of wheat 124 125 flour (wet basis) and 50 g/100 g pre-dissolved sugar solutions were mixed by hand with a 126 spatula to form a homogeneous paste, and then allowed to stand at room temperature overnight. Pre-dissolved sugar solutions were used to avoid the endothermic peak caused by 127 128 the dissolution of sugar during heating. Approximately 35-40 mg of each 3-component mixture were transferred to a T-zero aluminium DSC pan and hermetically sealed. Each 129 sample was heated in the DSC instrument (TA-Q2000 DSC, TA Instruments, New Caste, 130 131 Germany) from 30 °C to 130 °C with a 10 K/min heating rate. An empty DSC pan was used as a reference. Calibration was performed using indium and sapphire. Onset, peak, and end 132 gelatinisation temperatures were calculated by analysing the glass transition of the starch 133 (Slade & Levine, 1991). Gelatinisation enthalpy was calculated by integrating the exothermic 134 135 peak. Both analyses were conducted using TA Instruments Universal Analysis 2000 Software 136 (version 4.5A). Three replicates were performed on each sugar-containing sample (sucrose, 137 D-allulose, and D-fructose).

138 2.3. Preparation of Cupcake Batter and Baking Procedure

139 Cupcake batters were prepared using a multi-stage mixing method in a free-standing electric

- 140 mixer (Chef XL KVL4100W, Kenwood, Havant, UK) with a K beater attachment. The recipe for
- 141 pound cake described by Wilderjans, Pareyt, Goesaert, Brijs, and Delcour (2008) was

142 followed. Ingredient quantities are summarised in Table 2, no water was added as an

143 ingredient in batter formulation. Each batter was prepared by creaming the margarine and

one of the three sugars (sucrose, D-allulose, or D-fructose) in the mixer on speed 4 (central

- rotation: 130rpm and attachment rotation: 315 rpm) for 3 min. Liquid whole egg was then
- added and mixed on speed 3 (central rotation: 115 rpm and attachment rotation: 270 rpm)
- 147 for 30 s. Finally, flour, salt, and baking powder were added and mixed on speed 3 for 3 min.
- 148 Each section of a 12-hole cupcake tray was lined with a paper case and filled with batter to a
- 149 weight of 50.5 g ± 0.1 g. Each individual cupcake tray was then placed in the centre of a pre-
- heated oven (Stratos 3STA 4676 H18 S.207, Polin, Verona, Italy), set to 180 °C with a heat
- distribution of 40%:60% (top:bottom), and baked for the selected time (12 min, 16 min, and
- 152 20 min). Cupcakes were cooled for 1 h at room temperature, then placed in polyethylene
- 153 bags, and stored at room temperature for subsequent analysis.
- 154 A total of 9 cupcake formulations was assessed by combining each of the 3 sugars (sucrose:
- 155 S; allulose: A; fructose: F) with each of the 3 baking times (12 min: 12; 16 min: 16; 20 min:
- 20). These 9 samples were named with the initial of the sugar used, followed by the number
 of the baking time applied; for example: sucrose sample baked for 12 min = S12. All samples
 were prepared in duplicate.
- 159 2.4. Water Activity of Sugar Solutions and Cupcake Crumb

Equal weights of water and sugar were mixed by hand with a spatula to create a 50 g/100 g sugar solution, and then allowed to stand at room temperature overnight. Approximately 10 ml of the fully dissolved sugar solution were pipetted into the sample cup of an a_w-meter (HygroLab C1, Rotronic AG, Basserdorf, Switzerland), and water activity was measured at room temperature (20 °C) using the 'AwQuick' setting. Three replicates were performed on
each sugar (sucrose, D-allulose, and D-fructose).

The cupcakes were milled to a fine crumb and mixed. A fine layer of milled crumb was added into the sample cup of the a_w-meter, and water activity was measured at room temperature (20 °C) using the 'AwQuick' setting. Measurements were performed in triplicate.

- 169 2.5. Apparent Viscosity of batters
- 170 The apparent viscosity of the cupcake batters was measured following Tsatsaragkou,
- 171 Methven, Chatzifragkou, and Rodriguez-Garcia (2021) method with some modifications. An
- 172 oscillatory rheometer (MCR 302, Anton Paar Ltd., St Albans, UK) was used. Cupcake batters
- 173 with no leavening agent were allowed to rest in the measuring cell for 15 min equilibration
- time at 25 °C. Parallel serrated plate geometry (50 mm diameter; profile 1 mm x 0.5 mm)
- 175 was employed. Apparent viscosity was measured as a function of shear rate over the 0.1 to
- 176 100 s-1 range, at 25 °C. Data were fitted to the following power law (Ostwald model):

177
$$\eta = K \cdot \gamma^{(n-1)}$$

- 178 where η is the viscosity (Pa·s), γ is the shear rate (s–1), K is the consistency index (Pa·sn), and
- *n* is the flow behaviour index. Two batches of each cupcake batter were analysed.
- 180 2.6. Weight Loss During Baking
- 181 The weight loss during baking was calculated for each cupcake using the following equation
- 182 (Martínez-Cervera, Salvador, Muguerza, Moulay, & Fiszman, 2011):

183
$$W_{loss}(\%) = \left[\frac{W_{batter+case} - W_{cake+case}}{W_{batter+case}}\right] \times 100$$

where W_{loss} is the percentage weight loss during baking, $W_{batter+case}$ is the weight (in grams) of batter in its case before baking, and $W_{cake+case}$ is the weight (in grams) of the cupcake in its case after baking and cooling.

187 2.7. Cupcake Height

188 Four cupcakes were cut in half, on a plane perpendicular to their base (vertical axis), with a

189 stainless-steel knife and scanned (HP Scanjet G2710, HP Inc., Palo Alto, CA, USA). The

190 maximum cupcake centre height was measured from the scanned image, using ImageJ

191 software (National Institutes of Health, Bethesda, MD, USA).

192 2.8. Cellular Structure of the Cupcake Crumb

193 Each of the four images used to measure cupcake height was cropped, to a 5 x 3 cm section

194 from the central area of the cupcake, for crumb cell analysis with the ImageJ software

195 (National Institutes of Health, Bethesda, MD, USA). First, the image colour channels were

split to access the blue channel. The contrast was then enhanced by 0.4%, and finally the

image was binarized after grayscale threshold. Average cell size (in mm²) and total cell area

198 within the crumb (in percent) were calculated (Rodríguez-García, Sahi, & Hernando, 2014).

199 2.9. Cupcake Texture

200 For the evaluation of cupcake crumb texture, a cylindrical piece of crumb (4 cm diameter, 2

201 cm height) was taken from the centre of each of four cupcakes, with the aid of a stainless-

202 steel cutter. Texture measurements were carried out using a Texture Analyser (TA-XT2, Plus-

203 Upgrade, Stable Micro Systems, Godalming, UK) coupled with Exponent Connect Lite

software (version 6.1.16.0, Stable Microsystems). The instrument was equipped with a 5 kg

205 load cell and a cylindrical 75 cm diameter compression probe attachment (SMS P/75). A

206 double compression test was performed with a test speed of 1 mm/s, and the maximum deformation was 40% of the original cylinder height. The interval between two successive 207 208 compression cycles was 5 s, and a trigger force of 5 g was selected. From the force-time 209 curves of the Texture Profile Analysis, the parameters of hardness (maximum peak force 210 during the first compression cycle), springiness (distance of the detected height during the 211 second compression divided by the original compression distance), and cohesiveness (ratio 212 of the positive force area during the second compression to that during the first compression) were calculated by the software Exponent (version 6.1.18.0, Stable Micro 213 214 Systems, UK).

215 2.10. Cupcake Colour

216 The colour of both the crumb and crust of four cupcakes (per sugar) was measured using a 217 colorimeter (Chromameter CR-400, Konica Minolta, Tokyo, Japan). The results were 218 expressed in accordance with the CIELAB system (illuminant C and 10° viewing angle). The parameters measured were L* [indicates lightness and ranges from 0 (for black) to 100 (for 219 white)], a* [ranges from -a* (for greenness) to +a* (for redness)], and b* [ranges from -b* 220 (for blueness) to +b* (for yellowness)] (Konica Minolta, 2007; Wu & Sun, 2013). The 221 222 colorimeter was standardised with a white plate, and the colour of the crust was measured 223 at the centre point of the cupcake top. The cupcake was then cut in half on a plane parallel 224 to its base, and the colour of the crumb was measured at the centre point of the cut surface. 225 The browning index (BI), which represents the purity of brown colour, was calculated for 226 cupcake crust, as follows (Palou, López-Malo, Barbosa-Cánovas, Welti-Chanes, & Swanson, 1999): 227

228
$$BI = \frac{100(x - 0.31)}{0.172}$$

229 where:

230
$$x = \frac{a^* + 1.75L^*}{5.645L^* * + a^* - 0.3012b^*}$$

Total colour difference (ΔE^*) values were calculated for the crust and crumb of cupcakes baked for the same amount of time, in comparison to the sucrose samples (S12, S16, and S20). ΔE^* was calculated according to the following equation (Francis & Clydesdale, 1975):

234
$$\Delta E^* = \sqrt{(L^* - L_0^*)^2 + (a^* - a_0^*)^2 + (b^* - b_0^*)^2}$$

235 The values used, to determine whether total colour differences between cupcakes were

- appreciable by the human eye, were the following (Bodart, de Peñaranda, Deneyer, &
- 237 Flamant, 2008):
- 238 $\Delta E^* < 1$ colour differences are not obvious to the human eye.
- 239 $1 < \Delta E^* < 3$ colour differences are not appreciated by the human eye.
- 240 $\Delta E^* > 3$ colour differences are obvious to the human eye.
- 241 2.11. Asparagine and Acrylamide Analyses
- Asparagine and acrylamide were measured using the method described by Halford et al.
- 243 (2012). A flour sample $(0.100 \pm 0.005 \text{ g})$ was weighed into a 14 mL screw-top bottle.
- 244 Hydrochloric acid (10 mL, 0.01 mol/L) was added to the vial, and the sample was stirred for
- 245 15 min at room temperature. An aliquot of supernatant (2 mL) was centrifuged at 10000g for
- 246 10 min. The amino acids in 100 μ L of the centrifuged supernatant were then derivatized
- 247 using the EZ-Faast amino acid derivatization technique for GC-MS (Phenomenex, Torrance,
- 248 CA, USA). GC-MS analysis of the derivatized sample was carried out using an Agilent 5975

system (Agilent, Santa Clara, CA, USA). Three replicates were performed for UK plain flour.
Asparagine was quantified using a external calibration curve, prepared using a derivatized
amino acid standard.

252 For acrylamide extraction milled cupcake samples $(1.00 \pm 0.01 \text{ g})$ were weighed into 50 ml 253 Falcon tubes. Samples were extracted with 40 ml of deionised water containing 2 ml of internal standard $(1,2,3^{-13}C_3$ -acrylamide 1 mg/L) at room temperature. Each sample was 254 255 shaken in a mechanical shaker (Hei-MIX Multi Reax, Heidolph Instruments, Schwabach, 256 Germany) for 20 min at 1800 rpm, and then centrifuged (Sigma 3k10, Osterode am Harz, 257 Germany) at 15 °C and 9000 rpm for 10 min. Two mL were removed from the aqueous layer and passed through a 0.22-um pore size syringe filter into a 2-mL vial. All samples were 258 259 extracted and analysed in triplicate.

260 Cupcake crumb samples were analysed by liquid chromatography-mass spectrometry/mass 261 spectrometry (LC-MS/MS), using an Agilent 1200 High-Performance Liquid Chromatography 262 (HPLC) system, connected to a 6410 triple-guadruple mass spectrometer with electrospray ion source in positive ion mode (both Agilent Technologies, Santa Clara, CA). The mobile 263 phase was 0.1% aqueous formic acid at a flow rate of 0.3 mL/min. The injection volume was 264 265 5 μ L. An isocratic separation was carried out at room temperature, using a 100 x 3.0 mm Hypercarb column with a 10 x 3.0 mm Hypercarb pre-column (both 5 μ m particle size; 266 267 Thermo Fisher Scientific, Waltham, MA). The transitions m/z $72 \rightarrow 55$ and m/z $72 \rightarrow 27$ were measured for acrylamide, and the transition m/z 75 \rightarrow 58 was measured for ¹³C₃-acrylamide. 268 Concentrations of acrylamide in cupcake crumb samples were expressed as µg/kg fresh 269 270 weight, calculated from a calibration curve prepared from solutions in water containing 1

271 μ g/L, 2.5 μ g/L, 5 μ g/L, 10 μ g/L, 25 μ g/L, and 50 μ g/L acrylamide, alongside 50 ug/L ¹³C₃-272 acrylamide .

273 2.12. Statistical Analysis

274 Statistical analysis of the data was carried out using an XLSTAT (2020) software package (Addinsoft, France). The effect of sugar type on water activity, DSC starch gelatinisation 275 276 behaviour, batter consistency index and flow behaviour index was determined by one-way 277 ANOVA. The effect of sugar type and baking time on cupcake properties (water activity, 278 weight loss during baking, cell crumb structure, texture, height, colour and acrylamide content) was determined by two-way ANOVA. Multiple pairwise comparisons were 279 280 performed using Tukey's Honest Significant Difference (HSD) to evaluate mean value differences (p<0.05). 281

282 3. Results and Discussion

283 3.1 Starch Gelatinisation

Figure 1 shows that the DSC thermograms of wheat flour samples with the different sugars 284 had the melting transition at higher temperatures than the wheat flour and water sample. 285 286 The DSC results (Table 3) also showed that sucrose was able to shift starch gelatinisation to 287 higher temperatures than D-allulose and D-fructose. The sucrose solution-wheat flour sample had significantly higher onset, peak, and end gelatinisation temperatures (p<0.05), 288 compared to those of the D-fructose solution-wheat flour and D-allulose solution-wheat 289 290 flour samples, in good agreement with previously reported results (E. J. Lee et al., 2020; 291 Slade & Levine, 1991; Young et al., 2016). Several hypotheses have been proposed to explain 292 the influence different sugars have on the gelatinisation temperature of wheat starch. One 293 of the early theories, as reviewed by Slade and Levine (1991), attributes the effect sucrose

294 has on reducing water activity to its ability to retard wheat starch gelatinisation, through 295 limiting the availability of water to starch (Derby, Miller, Miller, & Trimbo, 1975) and thus delaying granule swelling. However, if water activity were the factor controlling starch 296 gelatinisation temperature, it would have been expected, based on our DSC results, that a 297 298 sucrose solution would have a lower water activity than a solution of D-allulose of the same 299 concentration. However, the opposite trend was observed (Table 3); the water activity of the 300 50 g/100 g D-allulose solution was significantly lower (p<0.05) than that of the 50 g/100 g 301 sucrose solution. However, the DSC results in Table 3 could be explained by an alternative theory, whereby the effectiveness of water or an aqueous sugar solution, acting as a 302 plasticiser, in lowering the glass transition temperature (Tg) of the amorphous regions of 303 304 starch, which represents the beginning of the starch gelatinisation process and thereby 305 precedes and controls the subsequent melting of starch crystalline regions, is determined by 306 the weight-average molecular weight of the sugar-water solvent, and thus follows the order water > monosaccharide > disaccharide, such that the resulting starch gelatinisation peak 307 308 temperature in water or sugar solution, which follows immediately after the onset Tg of the 309 plasticised amorphous starch, follows the order water < monosaccharide (e.g. D-allulose and 310 D-fructose) < disaccharide (e.g. sucrose) (Slade & Levine, 1991). Moreover, studies by Renzetti, van den Hoek, and van der Sman (2020, 2021); van der Sman and Mauer (2019) 311 312 have demonstrated that the elevation of melting (phase transition) temperatures of biopolymers, such as egg protein and starch, in the presence of sugars, is a function of the 313 volumetric density of intermolecular hydrogen bonds between water-sugar solution and the 314 315 biopolymer. Differences in molar volume (V) and effective numbers of hydroxyl groups 316 available for intermolecular hydrogen bonding (N_{OH,s}) define the volumetric density of 317 hydrogen bonding sites available in solution (sugar solution) for interactions with starch

318 $(\Phi_{w,eff})$ (Renzetti et al., 2020, 2021). Sucrose has a higher molar volume and effective number of hydroxyl groups available for intermolecular hydrogen bonding (N_{OH,s}) (210.2 cm³/mol, 319 4.48, respectively) than fructose (110.4 cm³/mol, 3.98, respectively) (Allan, Chamberlain, & 320 Mauer, 2020; Renzetti et al., 2020) (the authors could not find data on D-allulose molar 321 volume and N_{OH.s}). Thus, it has been hypothesised that, after these sugar solutions penetrate 322 323 the amorphous phase of the starch granules, the disaccharide solution would form more 324 hydrogen bonds with the amorphous phase and thereby increase the melting point of the crystalline regions of the starch to a greater extent than would the monosaccharide 325 326 solutions (Allan, Rajwa, & Mauer, 2018; van der Sman & Mauer, 2019). These theories could 327 explain why D-allulose and D-fructose, monosaccharides, were not able to increase the starch gelatinisation temperature as effectively as did sucrose. 328 329 Although our study did not examine the thermal setting process involving the denaturation

330 of egg protein, previous research has demonstrated that $\Phi_{w,eff}$ also controls this phase transition (Renzetti et al., 2020). Slade et al. (2021) have previously analysed by DSC, with 331 332 regard to 1:1 w/w samples of egg white protein in water alone or concentrated sucrosewater solutions. The thermogram curves showed that as the sucrose solution concentration 333 increased, the denaturation peak for ovalbumin increased (Slade et al., 2021). Moreover, it 334 335 has been demonstrated that at intermediate sugar concentrations (37-60%), close to a cake 336 system, and when the number of effective hydroxyl groups per molar volume of the 337 plasticisers (N_{OH} , s/v_s) increase, a separation of the ternary system protein/water/plasticiser 338 occurs, resulting in a biopolymer-rich phase and a plasticiser-rich phase, with water partitioning between the two domains; this gives place to a reduction in the effective 339 hydrogen bond density in the protein-rich domain, resulting in an elevation of the 340 341 denaturation temperature (Renzetti et al., 2020, 2021). Low molecular weight plasticiser

have $N_{OH,S}/v_s > 29$ and high molecular weight plasticiser have $N_{OH,S}/v_s < 10$. Therefore, it can be hypothesised that D-allulose and D-fructose will increase the denaturation temperature of egg white protein by phase separation in cake-type systems. This mechanism has not been proven in starch gelatinisation (Renzetti et al., 2021).

346 Although both D-allulose and D-fructose are monosaccharides with the same molecular weight, the D-fructose solution-wheat flour sample had significantly higher onset 347 348 and peak gelatinisation temperatures (p<0.05), compared to those for the D-allulose 349 solution-wheat flour sample, so that D-allulose was the least effective of the three sugars at 350 retarding starch gelatinisation. The reason for this difference might lie in the structural forms these sugars can assume, once dissolved in solution. When sugar molecules are dissolved in 351 352 aqueous solutions, a series of reactions involving molecular rearrangements takes places 353 around carbon 1, leading to the formation of a mixture of products that are in equilibrium; 354 this is called mutarotation (Cui, 2055). A study by Que and Gray (1974) found that, at equilibrium, in aqueous solutions at 30°C, D-fructose exists mainly in the β -pyranose ring 355 356 form, whereas the majority of D-allulose exists in the α -furanose ring form. Therefore, based 357 on the sugar-starch interaction theory mentioned above, it could be hypothesised that the 358 β -pyranose ring structure of D-fructose forms stronger bonds with the amorphous regions of 359 starch, compared to those formed by the α -furanose ring structure of D-allulose. However, 360 such an explanation for the observed order of these sugar solutions in retarding wheat starch gelatinisation is only speculation, so further investigation would be required to 361 support it. Alternatively, to distinguish between sugars of equal molecular size and weight 362 (e.g. monosaccharides such as D-allulose and D-fructose), with regard to their effect on 363 starch gelatinisation temperature, Slade and Levine (1991) proposed that the Tg of the sugar 364 365 could be the determining factor. In the present case, the order of increasing starch

gelatinisation temperatures measured for the 3-component mixtures listed in Table 3, and
likewise previously reported by E. J. Lee et al. (2020) and Young et al. (2016), i.e. D-allulose <
D-fructose < sucrose, does in fact match the order of Tg' values previously reported for the
three sugar solutions, i.e. D-allulose (-44 °C) < D-fructose (-42 °C) < sucrose (-32 °C) (Slade &
Levine, 1991).

371 3.2. Water Activity of Cupcakes

No significant interactions (p<0.05) were observed between sugar type and baking time, 372 373 when water activity values of the cupcakes were determined (Figure 2A and 2B). Cupcakes formulated with D-allulose and D-fructose had significantly lower water activity values 374 (p<0.05) than did those formulated with sucrose, which mirrors the water activity findings 375 376 for these sugars in solution (Table 3). D-allulose and D-fructose have one more hydroxyl group than sucrose, thus they can form more hydrogen bonds with water increasing their 377 378 water solubility compared to that of sucrose (Table 1). Typically, sugars with high solubility in water and low molecular weight have the greatest effect on reducing water activity, through 379 their colligative effect in solution (Ergun, Lietha, & Hartel, 2010). 380 3.3 Weight Loss During Baking 381 382 Significant interactions were observed (p<0.05) between sugar type and baking time, when

383 weight loss during baking was studied (Figure 2C). The A12 and F12 cupcakes lost

significantly less weight (p<0.05), compared to the S12 cupcakes. As weight loss is a

consequence of water evaporation during baking (Dhen et al., 2016), these results indicate

that this process was occurring at a slower rate in D-allulose and D-fructose cupcakes, during

the initial stages of baking. It is possible that this was due to the greater water-holding ability

388 of these monosaccharides (Ergun et al., 2010). The water activity values for the D-allulose

389 and D-fructose solutions were significantly lower (p<0.05) than that for the sucrose solution (Table 3); consequently, there was less free water available in the D-allulose and D-fructose 390 cupcake batters (Table 1), so more energy was required to initiate water evaporation during 391 baking. Furthermore, based on colligative properties, due to their lower molecular weight, 392 393 D-allulose and D-fructose solutions have higher boiling points than do sucrose solutions of 394 equivalent weight percentage (Ergun et al., 2010). However, as baking time increased, the D-395 allulose cupcakes experienced an increase in the rate of weight loss, and consequently, the observed weight losses for the A20 and S20 cupcakes were not significantly different from 396 397 each other (p>0.05). This might be because longer baking times gave place to higher 398 temperatures in the crumb so a complete structural setting (starch gelatinisation and protein denaturation) and a higher rate of water evaporation, allowing further bubble expansion and 399 400 water to be lost through open air cells. The resulting starch-filled protein network is so stiff 401 that bubble expansion is constrained and air cells open, allowing steam to escape (van der Sman and Renzetti, 2020; Wilderjans et al. 2013). These results can be related to the 402 403 pictures of S20 and A20 cupcakes in which cell opening and channelling can be observed 404 (Figure 3)

D-fructose cupcakes, however, did not follow the same baking loss trend as the Dallulose cupcakes did, as baking time increased past 12 min. The F20 cupcakes experienced significantly more weight loss (p<0.05) than did both the S20 and A20 cupcakes. This finding differs from what has been reported in previous studies, in which cakes formulated with Dfructose did not differ significantly from those formulated with sucrose, both in terms of moisture loss during baking (Psimouli & Oreopoulou, 2012) and final moisture content (Kweon et al., 2016).

412 3.4. Batter Viscosity

Sucrose, D-allulose and D-fructose batters showed shear thinning behaviour (data not 413 shown). In the range of shear rates studied, all batters showed similar apparent viscosity 414 415 values (data not shown). The experimental data showed good fit to the Ostwald deWaele 416 model (R² 0.95-0.98); all batters showed similar consistency index (K) (data not shown). 417 Sucrose batters had a similar flow behaviour index (n) than D-allulose and D-fructose 418 batters; however, D-allulose batters showed a significantly higher *n* (values close to 1) than D-fructose, indicating that the batter behaved closer to a Newtonian fluid. Initial batter 419 viscosity has an impact on the amount of air occluded and retained in the batter during 420 mixing, the stability of the air phase during early stages of mixing, on the evolution of bulk 421 viscosity during heating and thus, on the final quality of an aerated baked product (Martínez-422 423 Cervera, Sanz, Salvador, & Fiszman, 2012). The results suggest that batters with the three 424 different sugars would have similar air phase occlusion and stability during the first steps of 425 the production process. However, very different cell expansion rate and structure setting 426 was observed (Figure 3) suggesting that the main effects of the different sugars in cupcake structure formation were during the baking process. 427

428 3.5. Cupcake Height and Crumb Cell Structure

There were significant interactions (p<0.05) between sugar type and baking time, when cupcake height and cell crumb structure were studied (Figure 4A, 4B, and 4C). The sucrose cupcakes were significantly taller (p<0.05) than the D-allulose and D-fructose cupcakes at all baking times. Total air cell area for S12 was significantly higher (p<0.05) than for A12 and F12 cupcakes. Moreover, the cell crumb structure of sucrose cupcakes did not experience significant changes over increased baking times. The thermosetting of the batter, along with

435 gas expansion, bubble rupture and gas release, define the final cell crumb structure and height of the cakes (Slade et al., 2021). In S20 samples there is an increase in the size of air 436 437 bubbles, due to CO₂ production, water evaporation and thermal expansion of the gases (50 °C) (van der Sman & Renzetti, 2020). Then the setting process of the batter starts; egg yolk 438 proteins denature, gluten thermosets, starch gelatinise, and egg white proteins denature 439 shortly after starch gelatinisation; in fact, it is a near-simultaneous occurrence of events 440 (Slade et al., 2021; van der Sman & Renzetti, 2020). Starch acts as a water-sink in cake and is 441 442 responsible for the transformation of a liquid foam into a solid foam (van der Sman & Renzetti, 2020; Wilderjans, Luyts, Goesaert, Brijs, & Delcour, 2010); starch swells and leaches 443 amylose. During the thermal setting, a co-protein network is formed via S-S bridges between 444 denatured proteins from the wheat flour, egg yolk, and egg white (Lambrecht, Deleu, 445 446 Rombouts, & Delcour, 2018; Slade et al., 2021). The thermoset foam-structure is composed 447 by swollen starch granules entrapped in a protein matrix, with liquid oil (partially) coating 448 the swollen granules, and air bubbles encapsulated by denatured and aggregated protein network (Slade et al., 2021; van der Sman & Renzetti, 2020). Upon further heating and 449 expansion, the bubble ruptures. Swelled starch granules, embedded in the protein network 450 as fillers, allow partial cell opening and provide resistance against normal forces avoiding 451 452 total collapse (Slade et al., 2021; van der Sman & Renzetti, 2020). The smaller cell areas and height for the A12 and F12 cupcakes than that for the S12 453 cupcakes might be related to the effect of monosaccharides (D-allulose and D-fructose) in 454

455 shifting starch gelatinisation and protein denaturation temperatures as discussed in section

456 3.1. Samples with D-allulose and D-fructose showed lower wheat starch gelatinisation

- 457 temperatures than sucrose samples (Tables 3). In addition, it has been previously
- 458 demonstrated that low molecular weight plasticisers increase egg white protein

459 denaturation temperature by phase separation more than high molecular weight ones (Renzetti et al., 2020). So, in D-allulose and D-fructose batters, starch gelatinisation started 460 earlier than in sucrose batters, initiating the thermal setting of the batter. In contrast, egg 461 white protein denaturation was delayed, increasing the separation of the onset 462 temperatures of the two main processes of the structure thermal setting: the starch 463 464 gelatinisation and the egg white denaturation. Figure 3 shows how the structure setting 465 process of the sucrose, D-allulose and D-fructose batters baked during different times. The setting happened first at the bottom of the cupcakes, then at the centre and top, in 466 agreement with what has reported before (Wilderjans et al., 2013). In A12 and F12 batters, 467 the earlier start of starch gelatinisation, the asynchronous protein denaturation event and 468 the short baking time, did not allow the structure to fully expand and set; thus, the cupcakes 469 470 collapsed and shrunk showing very dense crumbs and low heights (Figure 3). Low molecular weight plasticisers increase starch swelling and further solubilisation and leaching out of 471 amylose, than higher molecular weight plasticisers (Renzetti et al., 2020). Excessive starch 472 473 swelling with amylose leaching could hinder the formation of the protein network, as 474 previously observed with hydroxypropylated starches in cake systems (Wilderjans et al., 475 2010). Moreover, starch gelatinisation increases batter viscosity and shear modulus due to the swelling of the starch granules (van der Sman & Renzetti, 2020). This increase in viscosity 476 477 at earlier stages of baking could have limited the expansion of air cells. The impediments and delay in the formation of the co-protein network that would strengthen the cell walls, and 478 479 the excessive swelling of the starch granules embedded in the network, gave place to a cake-480 foam structure that was not able to withstand the increase in pressure in the expanding air 481 cells, thus cracks and channels could not be formed and the condensation of the water vapour from the gas reduced the pressure and the cake collapsed. These cake-baking 482

483 phenomena has been previously described and explained in detail by Slade et al. (2021); van
484 der Sman and Renzetti (2020); Wilderjans et al. (2013); Wilderjans et al. (2008).

485 The D-allulose and D-fructose cupcake heights increased significantly (p<0.05), as baking 486 time was increased from 12 to 20 min (Figure 4A). Both the total air cell area and average 487 cell size in the A20 and F20 cupcakes were significantly greater (p<0.05), compared to those 488 for the A12 and F12 cupcakes, respectively (Figure 4B and 4C). The air cells in the A20 and 489 F20 cupcakes were also of a significantly larger average size (p<0.05), compared to those in 490 the S20 cupcakes. These results suggest that volume expansion was continuing in the D-491 allulose and D-fructose cupcakes, whereas sucrose cupcake expansion had terminated, after 12 min of baking. There could be two, complementary, explanations for this continuing 492 493 expansion. Firstly, after 12 min of baking, the boiling point for water in the D-allulose and D-494 fructose cupcakes was achieved, thereby allowing the excess moisture to form water 495 vapour, thus resulting in further air cell expansion.

Secondly, it could be possible that longer baking times allowed for a complete 496 thermal setting process -involving wheat flour starch gelatinisation followed by egg protein 497 denaturation— in the D-allulose and D-fructose cupcakes. The asynchrony of starch 498 gelatinisation and protein denaturation will still be a limiting factor for the development of a 499 homogeneous cell crumb structure. The formation of the co-protein network, although 500 501 limited and at a later stage than the starch gelatinisation, would have allowed air cells to 502 rupture, gases to escape and cell channels to form. A20 and F20 had experienced sufficient moisture evaporation, so that the cupcake crumb structure was likely to be in a rubbery 503 504 (liquid) physical state, with a denatured egg protein-based network below its network Tg,

and thus supportive enough to be removed from the oven without collapse (Slade et al.,
2021) and resulting in more aerated cupcakes than at 12 min.

507 3.6. Cupcake Texture

508 Significant interactions were observed between sugar type and baking time, when textural 509 parameters were studied (Figure 4D, 4E, and 4F). The A12 and F12 cupcakes were significantly harder, less cohesive, and less springy (p<0.05) than the S12 cupcakes were. The 510 511 greater hardness values for the A12 and F12 cupcakes are suggested to be attributable to 512 their denser crumb structure, due to limited expansion of their air phase, and structural collapse, as described in section 3.4. It has been hypothesised that during the A12 and F12 513 514 thermal setting process, there was greater starch swelling and more amylose was leached than in S12 cupcakes. During cupcake cooling, leached amylose will retrograde faster; 515 retrograded starch network is assumed to contribute to crumb firmness (van der Sman & 516 517 Renzetti, 2020), this could explain why A12 and F12 cupcakes were harder than the S20 cupcakes were. Cohesiveness and springiness are generally thought to indicate the 518 development of internal bonding in the protein network (Kalinga & Mishra, 2009; van der 519 520 Sman & Renzetti, 2020); thus, the lower cohesiveness and springiness of the A12 and F12 521 cupcakes are related to the limited and weaker co-protein network formation during the thermal setting of these samples in comparison to S12. 522

The hardness of the D-allulose cupcakes decreased with increasing baking time, whilst their springiness and cohesiveness increased, meaning that, after 20 min of baking, none of the textural parameters of the D-allulose cupcakes were significantly different from those of the sucrose cupcakes (p>0.05). This may have been due to further volume expansion, moisture evaporation, and completion of thermal setting process.

Significant interactions were observed (p<0.05) between sugar type and baking time, when 529 530 cupcake colour and browning index were studied (Figure 5 and Figure 6A). Total colour 531 differences were also calculated at each baking time (Table 4). The browning index and all 532 colour parameters (L*a*b*) for the sucrose cupcake crumb and crust did not change 533 significantly over baking time (p>0.05). In contrast, both the crust and crumb of the A20 and 534 F20 cupcakes were significantly darker and redder (p<0.05) than the A12 and F12 cupcakes, 535 and the browning index values for the A20 and F20 cupcake crusts were significantly higher 536 than that for the S20 cupcake (p<0.05). At baking times of 16 and 20 min, the total colour differences between test cupcakes were appreciable by the human eye ($\Delta E^*>3$), when 537 538 compared to sucrose control cupcakes. This indicates that browning was occurring more 539 rapidly in the two ketohexose cupcakes, compared to in the sucrose cupcakes, which could 540 be attributable to an increased rate of the Maillard reaction. D-allulose and D-fructose, unlike sucrose, are reducing sugars, so they can participate directly in the Maillard reaction 541 542 with amino acids. Therefore, brown-coloured water-insoluble polymers known as melanoidins, which form during the final stage of the Maillard reaction, can be produced 543 544 more readily (Starowicz & Zieliński, 2019). Enhanced rate of Maillard reaction, leading to the 545 formation of brownish-coloured products, has also been widely reported for foods 546 reformulated with D-allulose, including meringues (O'Charoen et al., 2014) and butter 547 cookies (Sun et al., 2008). Caramelisation is another type of colour-forming reaction that can 548 take place on the surface of cupcakes during baking (Purlis, 2010). It may be that this reaction also occurred more readily in the D-allulose and D-fructose cupcakes, because, as 549 550 with the Maillard reaction, sucrose would first have to hydrolyse into its constituent

- monosaccharides, fructose and glucose, before subsequent caramelisation reactions could
 begin (Quintas, Brandão, & Silva, 2007).
- 553 3.8 Cupcake Acrylamide Concentration
- 554 In the context of the publication of studies speculating about a link between acrylamide and cancer in humans (Besaratinia & Pfeifer, 2007), the acrylamide level in cupcakes is 555 considered to be an important factor to consider. Acrylamide forms during high-temperature 556 baking and other food processing methods above 120 °C in foods high in carbohydrates from 557 558 the reaction between free asparagine and intermediates of the Maillard reaction; in fact, it is 559 known that acrylamide creation during baking depends in part on the asparagine content of the particular flour used (Chen, Wu, Fu, & Fan, 2020; Elmore, Koutsidis, Dodson, Mottram, & 560 Wedzicha, 2005). The free asparagine content in the UK wheat plain flour used, 0.27 (0.02) 561 (g/kg), was in the range of free asparagine values reported before in UK wheat flour 562 varieties, 0.21 (0.01) – 0.54 (0.02) (g/kg) (Hamlet, Sadd, & Liang, 2008). 563 Significant interactions were observed (p<0.05) between sugar type and baking time when 564 565 acrylamide concentration was studied (Figure 6B). There were no statistically significant differences in acrylamide concentration among the A12, F12, and S12 cupcakes (p>0.05). 566 However, the A20 and F20 cupcakes had significantly higher (p<0.05) acrylamide 567 568 concentrations, compared to those in the A12 and F12 cupcakes, whereas the acrylamide 569 concentrations in the S20 and S12 cupcakes were not significantly different (p>0.05), which suggests that, as baking time increased, the acrylamide concentration increased rapidly in 570 571 the D-allulose and D-fructose cupcakes, so that the A20 and F20 cupcakes ended up with 572 significantly higher (p<0.05) acrylamide concentrations than that in the S20 cupcakes. As acrylamide is a product of the Maillard reaction, formed when reducing sugars (such as D-573

574	allulose and D-fructose) react with the amino acid asparagine (Mottram, Wedzicha, &
575	Dodson, 2002), such as in wheat flour (Elmore et al., 2005), these findings further indicate,
576	as would be expected, that the Maillard reaction was occurring more readily in the D-
577	allulose and D-fructose cupcakes than in the sucrose (a non-reducing sugar) cupcakes.
578	Moreover, when acrylamide concentration was plotted against crust browning index, a good
579	linear correlation ($R^2 = 0.75$) was observed (Figure 6C). At all three baking times, the
580	acrylamide concentrations in the D-allulose and D-fructose cupcakes were not significantly
581	different from each other (p>0.05), indicating that these two monosaccharides behaved
582	similarly, with regards to their extents of Maillard reaction. This, too, would be expected, as
583	they both have the same number of carbonyl groups available to react with the amine group
584	of free amino acids, which is the vital first stage in these reactions (Davis, 1995).
585	Although, as mentioned above, the acrylamide concentrations in the D-allulose and D-
586	fructose cupcakes were significantly higher than that in the sucrose cupcakes at 16 and 20
587	min of baking (p<0.05), these acrylamide levels are considered to be unlikely to be of
588	concern. Cupcakes are not a food currently covered by EU Regulation 2017/2158 (European-
589	Union, 2017) however, comparing results in the current study to benchmark levels for
590	similar products shows that the acrylamide levels in the D-allulose cupcakes are still minimal.
591	For example, the highest recorded acrylamide concentration in the D-allulose cupcakes in
592	this study was 15.1 $\mu g/kg$, which is just 4% of the benchmark level of 350 $\mu g/kg$ for 'biscuits
593	and wafers'.

4. Conclusion

595 There were two major differences between the interactions that sucrose and D-allulose had
596 within the cupcake matrix. Firstly, D-allulose exhibited a greater water-holding ability than

597 that for sucrose; thus, cupcakes formulated with this monosaccharide experienced more limited water evaporation during early baking. Secondly, D-allulose did not retard starch 598 gelatinisation as effectively as sucrose did during baking, as it has a lower effective numbers 599 of hydroxyl groups available for intermolecular hydrogen bonding (N_{OH.s}) (Renzetti et al., 600 2021) than sucrose. However, as a monosaccharide, D-allulose, could have increased the 601 602 protein denaturation time by phase separation (Renzetti et al., 2020) giving place to an 603 asynchronous thermal setting of the cupcake batter. These changes in the main phase 604 transitions during cupcake baking could have given place to an excessive starch swelling and amylose leaching and a limited formation of a co-protein network; thus, giving place to 605 dense and compact cupcakes with higher hardness and lower cohesiveness and springiness 606 607 than sucrose cupcakes. Additional studies would be needed to determine if the use of D-608 allulose could extend the shelf-life of cupcakes beyond that of traditional sucrose cupcakes and sensory experiments should be considered to determine sensory profile and 609 acceptability of D-allulose cupcakes. Further research on cupcake reformulation strategies 610 611 should be conducted to study combination of sugar replacers that create the conditions 612 $(\Phi_{w,eff})$ and have the properties (molecular weight, N_{OH,s}) (Renzetti et al., 2021) to successfully replace sucrose in high moisture aerated systems like cupcakes Moreover, there 613 614 are further opportunities for the use of this ultra-low-calorie sugar in other baked goods, which do not rely as heavily on water evaporation and volume expansion during processing 615 for their final product quality. Biscuits, for example, which contain less water in their doughs 616 617 and finished products, rise only slightly during the baking process, and experience limited starch gelatinisation during the baking process (Kweon et al., 2014), would be interesting to 618 619 study further, using D-allulose as part of sucrose-reduced formulations, as previously 620 reported by Young et al. (2016).
