Abstract

Many scientists use coronal hole (CH) detections to infer open magnetic flux. Detection techniques differ in the areas that they assign as open, and may obtain different values for the open magnetic flux. We characterize the uncertainties of these methods, by applying six different detection methods to deduce the area and open flux of a near-disk center CH observed on 2010 September 19, and applying a single method to five different EUV filtergrams for this CH. Open flux was calculated using five different magnetic maps. The standard deviation (interpreted as the uncertainty) in the open flux estimate for this CH $\approx 26\%$. However, including the variability of different magnetic data sources, this uncertainty almost doubles to 45%. We use two of the methods to characterize the area and open flux for all CHs in this time period. We find that the open flux is greatly underestimated compared to values inferred from in situ measurements (by 2.2–4 times). We also test our detection techniques on simulated emission images from a thermodynamic MHD model of the solar corona. We find that the methods overestimate the area and open flux in the simulated CH, but the average error in the flux is only about 7%. The full-Sun detections on the simulated corona underestimate the model open flux, but by factors well below what is needed to account for the missing flux in the observations. Under-detection of open flux in coronal holes likely contributes to the recognized deficit in solar open flux, but is unlikely to resolve it.

Unified Astronomy Thesaurus concepts: Solar coronal holes (1484); Solar magnetic fields (1503); Interplanetary magnetic fields (824)

1. Introduction

The solar wind is a magnetized plasma that expands outward from the solar corona to fill the interplanetary space. It plays a key role in heliophysics, providing the medium by which solar-originating space weather-driving phenomena, such as coronal mass ejections and solar energetic particles, produce effects/impacts on Earth and on the surrounding space environment. The solar wind is approximately structured into two types: slow and fast with different sources (Schwenn et al. 1981). Fast solar wind streams are associated with recurrent geomagnetic activity (Neupert & Pizzo 1974) and are therefore of increased research interest. They have been identified to originate from deep within coronal holes (Krieger et al. 1973), where the predominantly open magnetic field allows plasma to escape easily (Altschuler et al. 1972). Along these open magnetic field lines, the density and temperature of the outflowing plasma falls rapidly with height,

causing a relatively low intensity emission of coronal holes (hereafter, CHs) in EUV and X-ray images, or correspondingly bright in He I 10830 absorption (Bohlin 1977). The bulk of the Sun's open magnetic flux that is measured in interplanetary space is therefore expected to originate from CH regions. However, recent investigations have shown that the open magnetic flux identified in CHs underestimates the open magnetic flux in the heliosphere deduced from in situ measurements by a factor of two or more, referred to as the “Open Flux Problem” (Linker et al. 2017; Lowder et al. 2017; Wallace et al. 2019). While the fast wind is associated with the CHs themselves, the more variable slow solar wind is associated with the CH boundaries. In one class of theories, the slow wind arises quasi-statically from regions of large expansion factor near the boundaries (Wang & Sheeley 1990; Cranmer et al. 2007). Interchange reconnection (reconnection between open and closed fields; Crooker et al. 2002) has been suggested as the source of a dynamic slow solar wind (Fisk et al. 1998; Antiochos et al. 2011) and would most easily occur near CH boundaries. Fisk & Kasper (2020) argue that recent measurements from Parker Solar Probe (PSP; Fox et al. 2016) show that open magnetic flux is transported by interchange

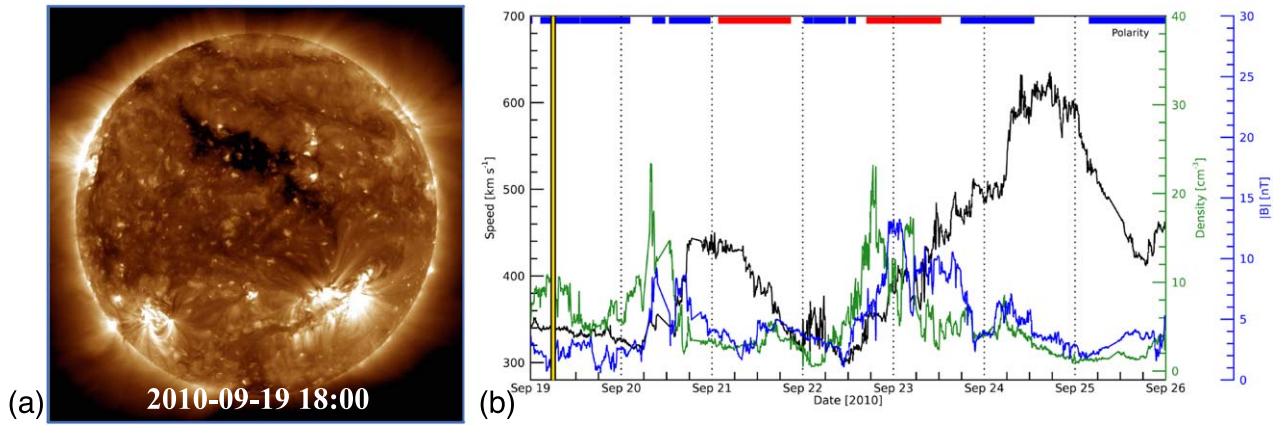

Figure 1. (a) AIA/SDO 193 Å full-disk image of the Sun on 2010 September 19. The CH selected for this study is easily visible in the northern hemisphere. (b) In situ signatures of the associated solar wind (data provided by the OMNI database), where the black line shows the solar wind bulk velocity, the green line represents the plasma density, and the blue line is the magnetic field strength. The red–blue colored bars on the top represent the polarity of the in situ measured magnetic field calculated after Neugebauer et al. (2002), with red being positive and blue negative polarity, and the time of the SDO observation corresponds to the yellow vertical line.

reconnection. Identifying and characterizing CHs and their boundaries is therefore crucial to understanding the origins of the solar wind and to assessing the uncertainties in the quantification of open magnetic flux.

The identification of CH regions is traditionally performed by visual inspection of image data (Harvey & Recely 2002). In recent years, several automatic or semi-automatic routines have been developed for more objective results (Henney & Harvey 2005; Scholl & Habbal 2008; Krista & Gallagher 2009; Rotter et al. 2012; Lowder et al. 2014; Verbeeck et al. 2014; Boucheron et al. 2016; Caplan et al. 2016; Garton et al. 2018; Heinemann et al. 2019). In combination with photospheric magnetic field data, the extracted CH area can be used to derive the open magnetic flux from that region. If a detection method allows a full-Sun map of CHs to be created for a given time period, then the solar open flux can be estimated entirely from observations by overlaying the CH map onto a synchronic or diachronic (often referred to as synoptic) magnetic map (Lowder et al. 2014; Linker et al. 2017; Wallace et al. 2019).

As identified by Linker et al. (2017), there are two general categories of resolutions for this underestimate of the open flux: (1) either the magnetic maps derived from observations are underestimating the magnetic flux, or (2) a significant portion of the open magnetic flux is not rooted in regions that appear dark in emission. Category (1) includes possible underestimates by the magnetographs, which often disagree quantitatively (e.g., Riley et al. 2014), or underestimates in specific regions, such as the poorly observed polar regions (Riley et al. 2019). Category (2) raises the important question of how well currently available CH detection methods perform and how they compare to each other.

To address and resolve this issue, we formed an International Space Science Institute (ISSI¹⁵) team, and we report the outcome of the first team meeting here. We study a well-observed low-latitude CH and its associated Carrington Rotation (CR), which occurred during solar minimum at the beginning of cycle 24 (CR2101, 2010 September 5–October 3). We investigate the uncertainties in the calculation of open magnetic flux from remote observations by exploring the variability in the results that occur when different CH detection

techniques, different wavelengths, instruments, and different photospheric magnetic maps, are used. As there is no “ground truth” measurement for the open flux on the Sun, we use a thermodynamic MHD model (e.g., Mikić et al. 2018) to simulate the corona for this time period and produce synthetic EUV emission images. The same analysis that was performed on the observations is repeated for the simulated data, where the “true” open flux is known. The observational and model results are related to in situ estimates of the heliospheric magnetic flux. From that we assess the overall ability of detection methods to account for solar open flux and identify potential sources of missing open flux.

2. Methodology and Data

We focus on one particular CH observed on 2010 September 19, and the surrounding time period (CR2101, 2010 September 5–October 3). We selected this time period and CH based on the following criteria: (i) availability of high-resolution Solar Dynamics Observatory (SDO)/Atmospheric Imaging Assembly (AIA) and low noise SDO/HMI data, (ii) a solar minimum time period, when there is less solar activity and the coronal configuration is simpler, (iii) an isolated CH, i.e., not connected to a polar coronal hole nor surrounded by strong active regions, at lower latitudes and with comparatively well-defined boundaries at the solar surface to minimize projection effects, and (iv) clear signatures of the associated high-speed stream from in situ data. Figure 1 shows the Sun on 2010 September 19 with the CH under study located in the central part of the solar disk (panel (a)) as well as the related solar wind high-speed stream at 1 au from in situ data (panel (b)).

2.1. CH Detection Methods

There are now several automated and semi-automated methods for detecting CH boundaries from emission images, and these are often used to identify regions of open magnetic flux. At the present time, the accuracy of these methods is unclear, and there has been little intercomparison between the methods. The uncertainty of these methods is therefore an open question that directly impacts the larger question of why coronal estimates of open flux disagree with inferences from in situ measurements.

¹⁵ <http://www.issibern.ch/teams/magfluxsol/>

We apply six different but commonly used methods to this CH, and estimate the uncertainties in CH detection, which in turn leads to uncertainties in the observed open flux. The extraction methods used are: simple thresholding (THR; Krista & Gallagher 2009; Rotter et al. 2012), the Spatial Possibilistic Clustering Algorithm (SPoCA; Verbeeck et al. 2014), Synchronic Coronal Hole Mapping (PSI-SYNCH; Caplan et al. 2016), the Minimum Intensity Disk Merge (PSI-MIDM; Caplan et al. 2019), the Coronal Hole Identification via Multi-thermal Emission Recognition Algorithm (CHIMERA; Garton et al. 2018), and the Collection of Analysis Tools for Coronal Holes (CATCH; Heinemann et al. 2019). The CH area extraction methods are applied on high-resolution EUV data in several wavelengths (171, 193, 211 Å) from AIA aboard SDO (Lemen et al. 2012). The 193 Å wavelength range is particularly favorable for the detection of CHs due to the strong contrast between the low intensity CH region and brighter surrounding quiet corona. In addition to AIA, we also use SWAP/PROBA2 174 Å (Seaton et al. 2013), XRT/HINODE (Golub et al. 2007), and 195 Å data from the EUVI instrument (Wuelser et al. 2004) aboard the STEREO spacecraft (Kaiser et al. 2008). The different algorithms and methods are briefly described below. Examples applying the different extraction methods are shown in Figure 2.

2.1.1. Simple Thresholding (THR)

Rotter et al. (2012) present a CH extraction method that applies simple intensity thresholding, based on work described in Vršnak et al. (2007) and Krista & Gallagher (2009). Following that approach, we use a threshold of 35% of the median solar disk intensity to extract dark coronal features from SDO/AIA 193 Å images. The 35% median intensity threshold has been found to give consistent and reasonable results for CH boundaries, especially near the maximum of solar cycle 24 (Hofmeister et al. 2017; Heinemann et al. 2019).

2.1.2. SPoCA

The SPoCA-CH-suite (Verbeeck et al. 2014) is a set of segmentation procedures that can decompose an EUV image into regions of similar intensity. It is typically used to identify active regions, CHs, and quiet Sun. It relies on an iterative clustering algorithm called fuzzy C-means, which minimizes the variance in each cluster. Typically, the CH class corresponds to the class whose center has the lowest pixel intensity value. The SDO Event Detection System runs the SPoCA-suite to extract CH information from AIA images in the 193 Å passband, and uploads the entries every four hours to the Heliophysics Events Knowledgebase (Hurlburt et al. 2012). The code for the SPoCA-suite is available at <https://github.com/bmampaey/SPoCA>.

2.1.3. PSI-SYNCH and PSI-SYNOPTIC

The goal of the PSI-SYNCH algorithm (Caplan et al. 2016) is to create, as accurately as possible, synchronic EUV and CH maps for the entire Sun. It was originally developed and applied to the 2010–2014 time period when most or all of the Sun was visible in EUV from the NASA STEREO and SDO spacecraft. All of the PSI methods emphasize pre-processing of the image data. PSI-SYNCH applies a point-spread function deconvolution to the full-disk images to remove stray light, especially in the CHs, and produces nonlinear limb brightening correction factors and inter-instrument transformation factors using a running one year

average of disk data. The CH detection is applied to each disk image using a dual-threshold region growing algorithm called EZSEG (image segmentation code). After the detection, the results for each disk are merged together into a single synchronic full-Sun CH map. Results, as well as the open-source EUV pre-processing and EZSEG codes are made available at <http://www.preds-ci.com/chd>. To produce EUV and CH maps that tend to be more continuous for dark structures, each disk image is first mapped to its own Carrington map. The three maps are then merged by incorporating the lowest intensity values of the overlap. For detection on the CH of interest, the maps are cut out in a $\pm 90^\circ$ longitude versus sine-latitude Stonyhurst heliographic projection.

PSI-SYNCH provides full-Sun synchronic maps for those time periods when combined SDO and STEREO images cover the entire Sun’s surface (2011–2014). In 2010 September, a portion of the Sun’s surface on the backside of the Sun was not visible from the STEREO spacecraft. Therefore, combined SDO and STEREO images cannot be used to generate a full-Sun map. To provide a full-Sun map for CR2101 from which we can estimate the Sun’s total open flux, we use PSI-SYNOPTIC. PSI-SYNOPTIC uses the same detection methodology, but instead combines images over an entire solar rotation, with pixels weighted in longitude by their proximity to disk center at the time of the observation. This diachronic map uses only SDO AIA observations.

2.1.4. PSI-MIDM

A challenge for CH detection and area extraction based on single images stems from the fact that EUV LOS observations flatten the three-dimensional structure in the low corona, which can cause nearby bright structures to obstruct CHs. To mitigate this obstruction, an alternative method to combine EUV disk images into a full-Sun map, referred to as the Minimum Intensity Disk Merge (MIDM), is used. This builds on the PSI-SYNCH and PSI-SYNOPTIC approaches, using an arbitrary number of vantage points and/or images over time. PSI-MIDM (Caplan et al. 2019) uses the same EZSEG algorithm as PSI-SYNCH for detection. Instead of using centrally weighted latitude strips, as in PSI-SYNOPTIC, MIDM takes full-disk images in the image- or time-sequence and merges them based on which pixels in the overlap exhibit the minimum intensity. This allows any part of the CH area observed from any vantage point or time in the image sequence to be seen in the final map. This can be performed even if only a single vantage point is available, by combining images taken over time (i.e., SDO AIA observations). This creates a trade-off between detecting rapid CH evolution versus revealing portions of CHs obscured by bright loops (as can occur near active regions). For this study, we created a PSI-MIDM map and detection using SDO AIA observations at a 6 hr cadence over all of CR 2101. As with PSI-SYNCH, a $\pm 90^\circ$ longitude versus sine-latitude Stonyhurst heliographic projection is used to focus on the selected CH.

2.1.5. CHIMERA

CHIMERA (Garton et al. 2018) uses the three SDO/AIA passbands where CHs are predominantly visible (171, 193, and 211 Å) to segment dark structures. The extraction is based on the ratios and magnitudes of the emission from each passband. CHIMERA is an automated CH detection and extraction

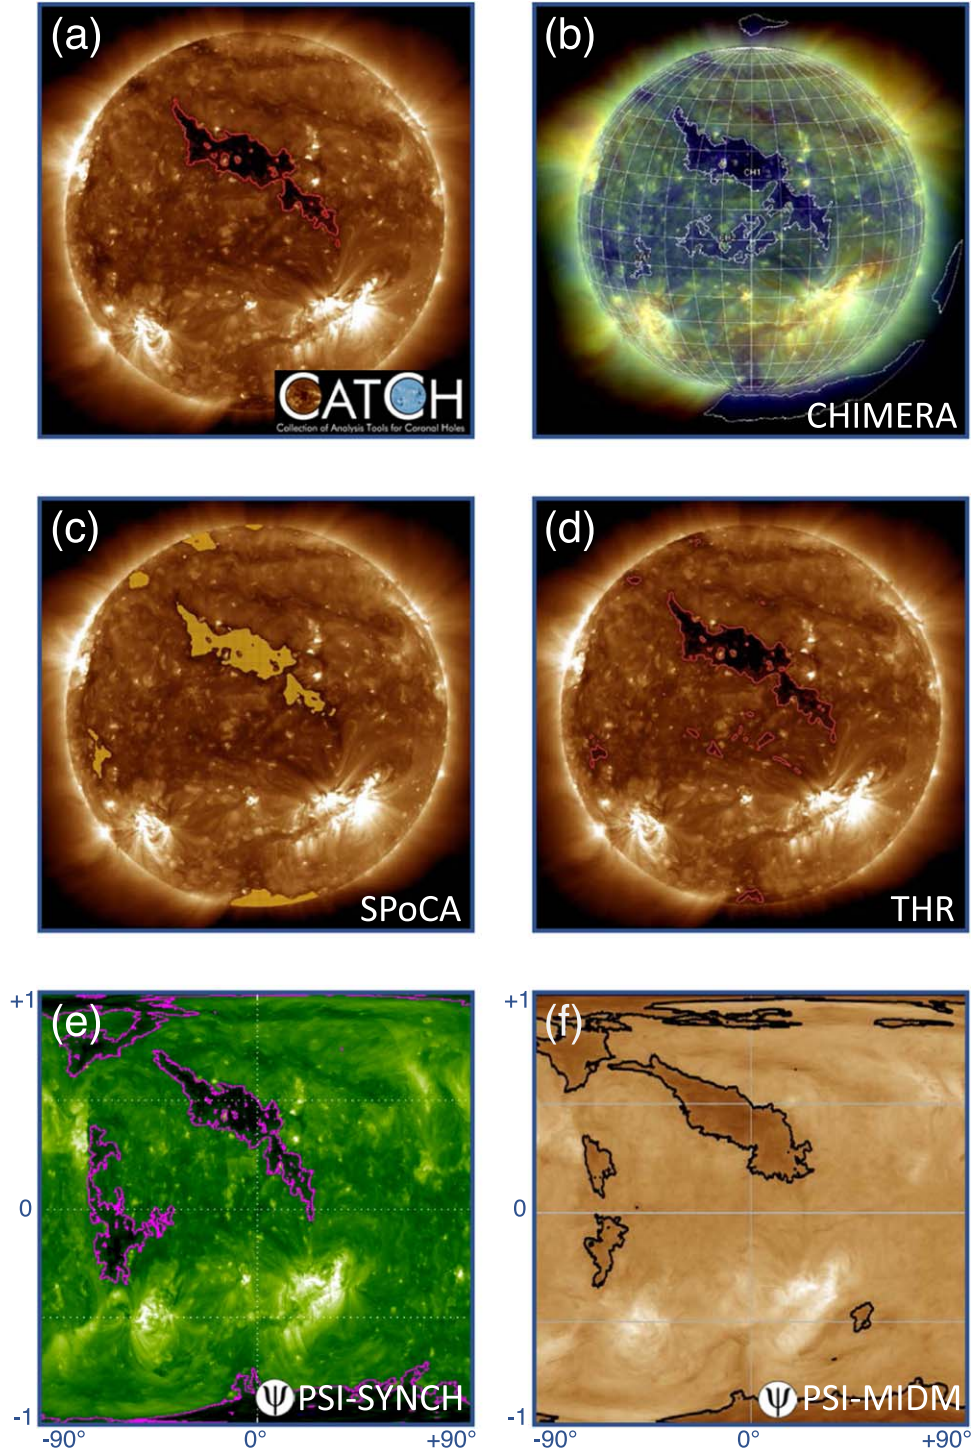

Figure 2. Examples of the CH detection and extraction methods used in this study applied on EUV image data. Images are for the CH of interest that crossed the central meridian on 2010 September 19. Panels (a) through (f) feature CATCH, CHIMERA, SPoCa, THR, PSI-SYNCH and PSI-MIDM, respectively. To focus on the CH of interest, full-Sun PSI-SYNCH and PSI-MIDM detection maps are cut out in a $\pm 90^\circ$ longitude vs. sine-latitude Stonyhurst heliographic projection.

algorithm and derives robust boundaries, which are continuously presented at solarmonitor.org.

2.1.6. CATCH

The recently developed CATCH algorithm (Heinemann et al. 2019) is a threshold-based CH extraction method, which uses the intensity gradient along the CH boundary to modulate the extraction threshold. By minimizing the change in the extracted

area between similar thresholds, a stable boundary can be found. CATCH also provides uncertainty estimations for all parameters. Due to its concept and setup, CATCH can be applied to any intensity-based EUV filtergram to extract low intensity regions on the solar surface. The tool is publicly available at <https://github.com/sgheinemann/CATCH>, including a link to the Vizier catalog—a sample of more than 700 CHs, ready for statistical analysis.

2.2. Open Flux Derivation at the Sun

Photospheric magnetic maps show significant variability, from both the underlying measurements at different observatories and the method of map preparation. To address and quantify this issue, we use five different magnetic map products to calculate the open flux within the extracted CH boundaries. We obtain an estimate of the open magnetic flux for each CH detection by overlaying the extracted CH boundaries on a photospheric magnetic map taken at approximately the same time as the emission images. We integrate the signed magnetic flux in each boundary (and also obtain the signed average magnetic field) for each detection, using synoptic maps of the photospheric magnetic field from three different observatories—Michelson Doppler Imager (MDI; Scherrer et al. 1995) aboard the Solar and Heliospheric Observatory (SOHO; Domingo et al. 1995), Helioseismic and Magnetic Imager (HMI; Schou et al. 2012) aboard SDO (720s-HMI), and the ground-based Global Oscillation Network Group instruments (GONG; Harvey et al. 1996). As these are derived from line-of-sight (LOS) magnetograms, the radial magnetic field (B_r) is obtained under the frequently used assumption that the field is radial where it is measured in the photosphere (Wang & Sheeley 1992). Additionally, we used magnetic maps generated with the Air Force Data Assimilative Photospheric flux Transport (ADAPT) model (Arge et al. 2010; Hickmann et al. 2015) using both HMI and GONG full-disk magnetograms as input, for a total of five different magnetic flux inputs. We note that the ADAPT model multiplied the HMI values by 1.35, and the GONG values by 1.85, prior to assimilation. All of the magnetic data were formatted to the same projection and resolution as the detected CH boundaries.

2.3. Derivation of the Heliospheric Magnetic Field

Spacecraft with in situ instruments directly measure the heliospheric magnetic field (HMF) at a single point in space. The unsigned magnetic flux threading a heliocentric sphere with measurement radius, r , can therefore be estimated by $\Phi_r = 4\pi r^2 |B_r|$, where B_r is the radial component of the HMF, if it is assumed that the single-point measurement of $|B_r|$ is representative of all latitudes and longitudes. From near-Earth space, the longitudinal structure of $|B_r|$ can be measured by considering an entire Carrington rotation period and assuming the corona and HMF do not evolve significantly over this time interval. Latitudinal invariance in $|B_r|$ (scaled for heliocentric distance) was confirmed by the Ulysses spacecraft on all three of its orbits (Lockwood et al. 2004; Smith & Balogh 2008). Thus the assumption that single-point measurements of the HMF can be used to estimate Φ_r appears to be valid. This has been demonstrated empirically by Owens et al. (2008). However, there is an additional issue that $\Phi_{1\text{ au}}$ may not be equal to the unsigned flux threading the solar source surface, Φ_{SS} , which is the typical definition of open solar flux. If the HMF becomes folded or inverted within the heliosphere, $\Phi_{1\text{ au}} > \Phi_{\text{SS}}$. As suprathermal electrons move anti-sunward on a global scale (Pilipp et al. 1987), sunward motion can be used to identify times when the HMF is locally folded (Crooker et al. 2004). For calculating the heliospheric magnetic field, we take in situ plasma and magnetic field measurements from the Advanced Composition Explorer (ACE; Stone et al. 1998) and its Solar Wind Ion Composition Spectrometer (SWICS; Gloeckler et al. 1998), Solar Wind Electron Proton Alpha Monitor (SWEPAM;

McComas et al. 1998), and Magnetometer Experiment (MAG; Smith et al. 1998). Two of the CH detection methods (PSI-MIDM and PSI-SYNCH/SYNOPTIC) provide CH detection and open flux estimates over the entire Sun’s surface. We employ these methods to estimate the amount of open flux in CR2101, and compare these results with estimates of the interplanetary magnetic flux for this time period.

2.4. Simulating the Open Flux at the Sun

While remote solar observations allow us to infer the open solar magnetic flux in the solar corona, we are not able to measure it directly. In an alternative approach, we employ a thermodynamic MHD model (e.g., Mikić et al. 2018) for CR2101, and we create a sequence of simulated AIA images for the same viewpoint of the real spacecraft over the course of the rotation. We apply the CH detection methods to the simulated data, and compare with the “true” open flux (known from the model) to further assess the effectiveness of detection methods in accounting for open flux. The thermodynamic MHD model is briefly described in the Appendix.

3. Inferring Open Flux from Coronal and Heliospheric Observations

3.1. Coronal Hole Detection

We performed six detections for the selected CH using CATCH, CHIMERA, PSI-SYNCH, SPoCA, THR and PSI-MDIM. The detections were each done using their native input data and projection. For intercomparison, the extracted CH boundaries were projected to Carrington longitude at 1° per pixel and heliographic sine-latitude at $\frac{1}{90}$ per pixel, and smoothed using spherical morphological operators of size 3 (Heinemann et al. 2019). The resulting maps contained equal area pixels of roughly $9.4 \times 10^7 \text{ km}^2$. The comparison between the extracted boundaries is shown in Figure 3. We find that the average extracted area is $8.89 \pm 2.35 \times 10^{10} \text{ km}^2$, with the SPoCA extraction providing the smallest value ($4.90 \times 10^{10} \text{ km}^2$), and the largest value ($11.94 \times 10^{10} \text{ km}^2$) obtained from the PSI-MIDM extraction. The areas of the maximum and minimum extractions differ by a factor of >2 , and the uncertainty, estimated as the standard deviation of the mean of all CH areas, is roughly $\sigma_{\text{A,d}} \approx 26\%$.

To further explore the uncertainties in CH detection, we investigated how the extracted CH boundary varied for different wavelengths and instruments. To accomplish this task, we used CATCH, which employs a detection methodology that performed close to the mean value of all of the methods (see Table 1) and moreover, is easily applicable to all intensity-based images. We applied CATCH to five sets of input data (193 Å AIA/SDO, 211 Å AIA/SDO, 195 Å EIT/SOHO, 174 Å SWAP/PROBA2, and XRT/HINODE). The comparison between the extracted boundaries is shown in Figure 4. We find the average detected CH area to be $7.83 \pm 2.00 \times 10^{10} \text{ km}^2$ for the five different data sets. The values range from $10.23 \times 10^{10} \text{ km}^2$ (from EIT 195 Å data) to $4.77 \times 10^{10} \text{ km}^2$ (from 174 Å SWAP data), which is about a factor of two. The uncertainty here is roughly in the same order as when using different extraction methods of about $\sigma_{\text{A,CATCH}} \approx 26\%$ of the mean. The low value obtained with the 174 Å wavelength should be viewed with some caution. This line forms at a lower temperature range and at lower coronal heights than the other lines, and therefore may image different structures in the CH.

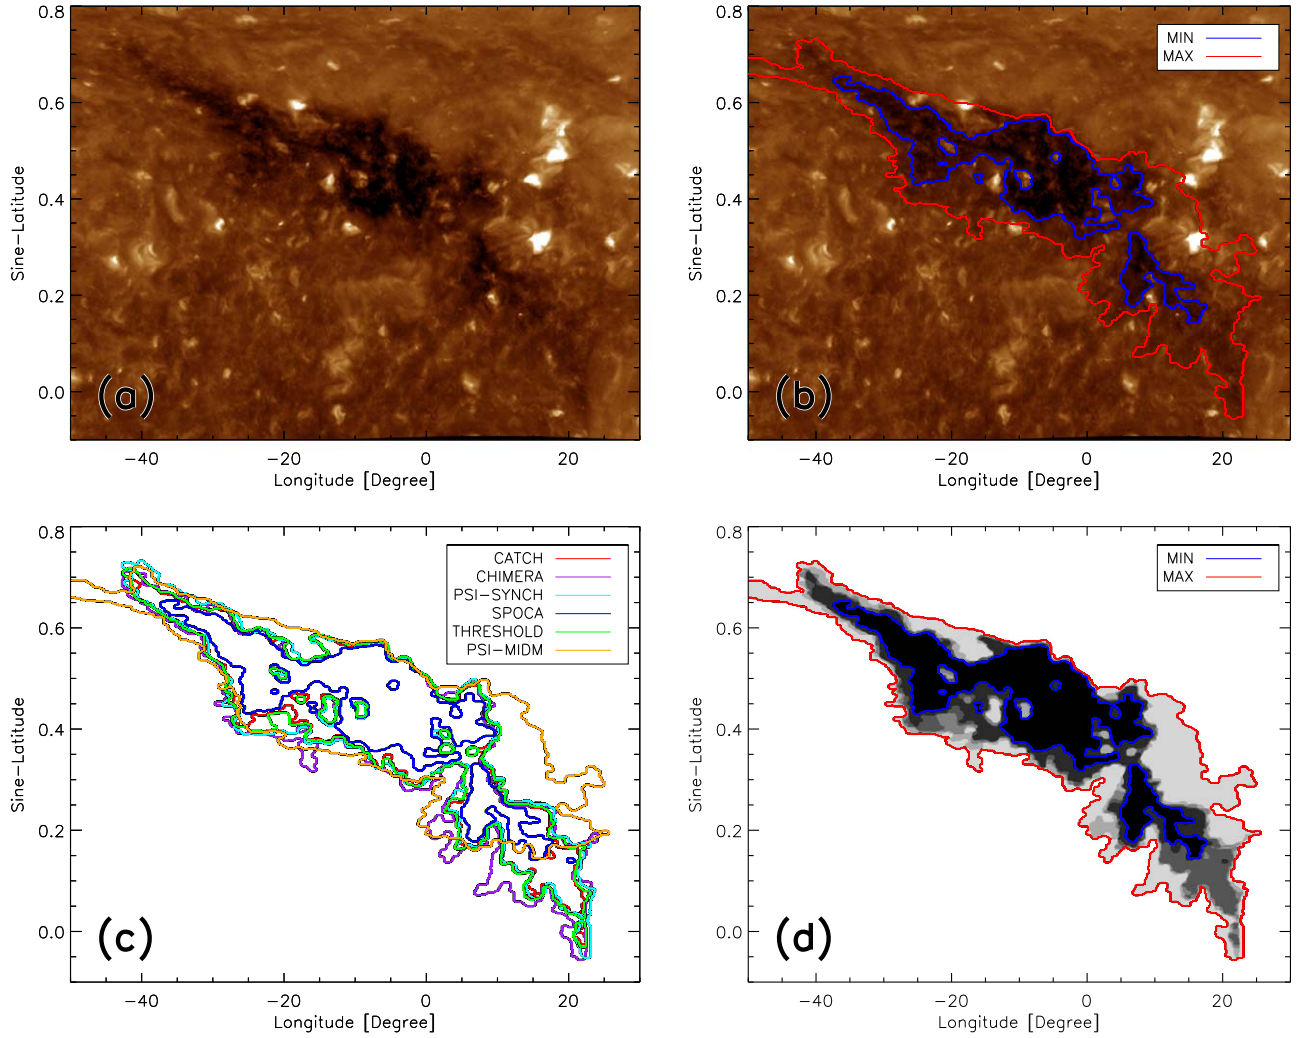

Figure 3. Detection of CH boundaries using different methods: (a) The AIA/SDO 193 Å filtergram. (b) The AIA/SDO 193 Å filtergram overlaid with the minimum and maximum boundary constructed by overlaying the six individual boundaries. (c) The extracted CH boundary from CATCH using AIA/SDO 193 Å; CHIMERA using AIA/SDO 171/193/211 Å; PSI-SYNCH using AIA/SDO 193 Å and EUVI/STEREO 195 Å; SPOCA using AIA/SDO 193 Å; thresholding (with 35% of the median solar disk intensity); and PSI-MIDM using multiple AIA/SDO 193 Å images. (d) Stacked map of the six binary extracted CHs. Darker pixels represent more agreement among the detections.

To calculate the open flux within the extracted CH boundaries, we employ five different photospheric magnetic maps (Section 2.2). To compute the open magnetic flux, we sum the magnetic field values from the selected magnetic map within the equal area pixels of the CH map (described at the beginning of this section). Therefore, the magnetic flux in a CH is computed at the same resolution for all magnetic maps, regardless of the resolution of the original map. We do not consider the noise levels of the different maps, but the signed magnetic flux is not likely to be sensitive to this quantity, as the noise will tend to cancel in the integral. For example, Caplan et al. (2021) recently showed that open magnetic flux is insensitive to resolution in Potential Field Source Surface (PFSS) models, over a wide range of scales. Figure 5 shows the five different magnetic maps (MDI, HMI, GONG, GONG-ADAPT, and HMI-ADAPT) overlaid with the minimum and maximum stacked CH boundaries.

When applied to an individual magnetic map, we find that the variations in the signed mean magnetic field density are rather small ($\sigma_{B_i} < 9\%$) between different extracted boundaries (varying both the detection method and the input data).

However, large deviations are derived between the different magnetic maps with a mean magnetic field density of -2.78 ± 0.67 G within a range of -2.0 to -3.5 G. This is equivalent to an uncertainty of $\sigma_B \approx 24\%$. When calculating the open flux from the CH area, A , and underlying magnetic field, B , as $\Phi = A \times B$ for each extraction and each map, we find an average of $(-23.59 \pm 10.75) \times 10^{20}$ Mx ($\sigma_{\Phi,d} \approx 46\%$) for the different CH extraction methods and $(-22.35 \pm 9.53) \times 10^{20}$ Mx ($\sigma_{\Phi,CATCH} \approx 43\%$) for the different input data with one extraction method. The values found range from -10.9×10^{20} Mx to -35.32×10^{20} Mx between all CH extractions.

Table 1 summarizes the CH properties using different extraction methods, magnetic field maps, and native input data. Table 2 lists the CH properties using CATCH with different input data and magnetic field maps. We see that the ADAPT maps (using either GONG or HMI magnetograms) generally provide the highest estimates of the mean magnetic field density and magnetic flux. This is likely due to the multiplication factors applied to the input magnetograms during assimilation, which is performed in part to counter perceived underestimates of the magnetic flux.

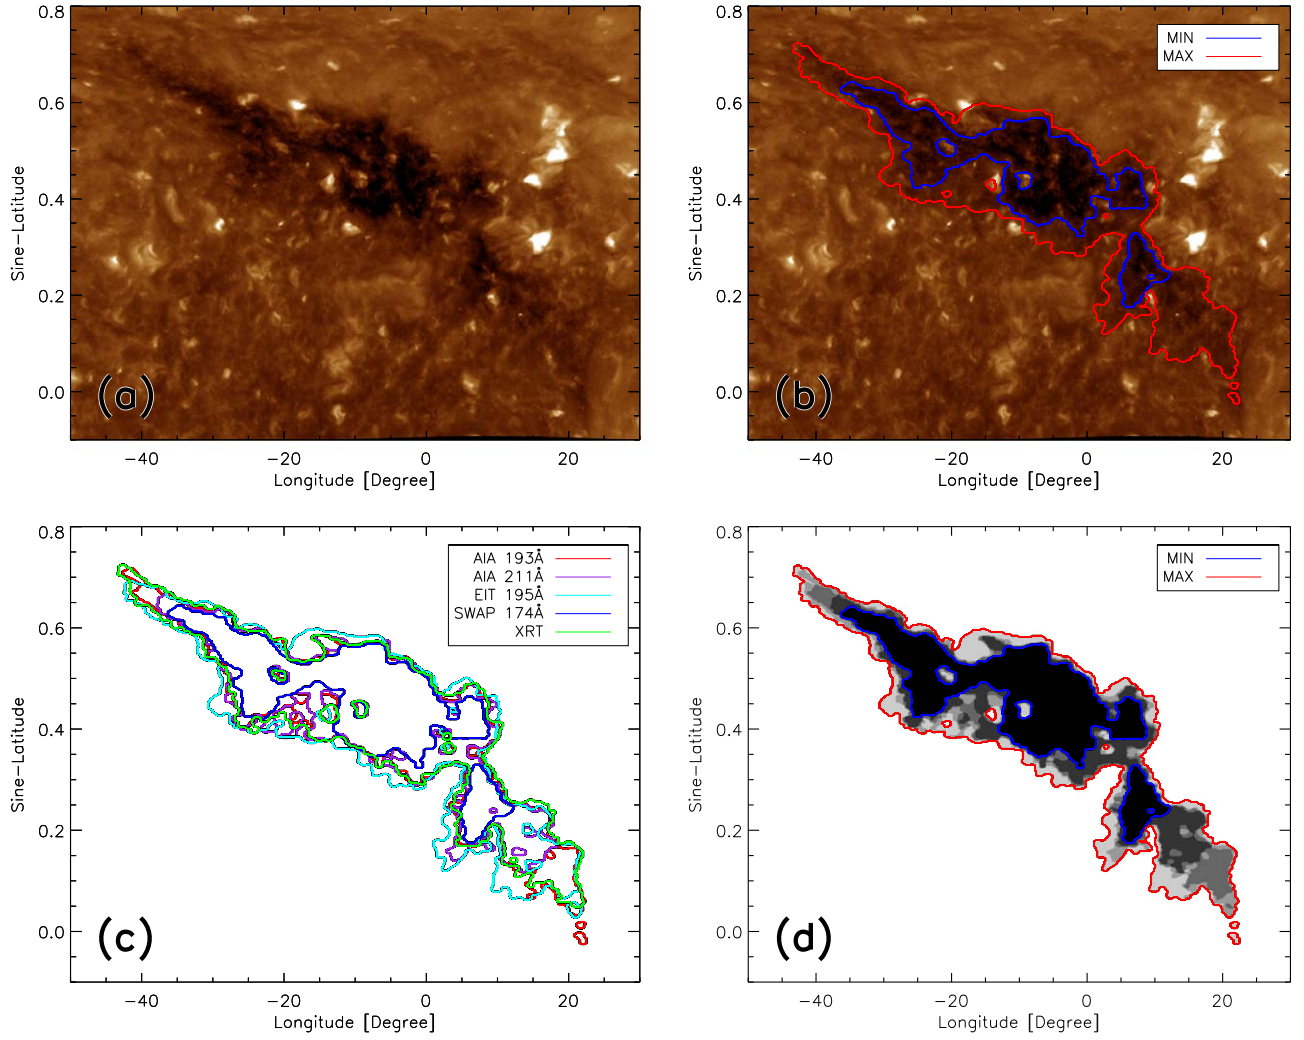

Figure 4. CH boundaries extracted using CATCH on different input EUV filtergrams. The panels show: (a) The AIA/SDO 193 Å filtergram. (b) The AIA/SDO 193 Å filtergram overlaid with the minimum and maximum boundaries constructed by overlaying the five individual boundaries. (c) The different boundaries extracted by the means of CATCH using input data from AIA/SDO 193 Å and 211 Å, EIT/SOHO 195 Å, SWAP/PROBA2 174 Å, and XRT/Hinode. (d) Stacked map of the five binary extractions (where darker pixels represent an agreement of more extractions).

Table 1
CH Parameters Derived from Different Extraction Methods (CATCH, CHIMERA, SPoCA, PSI-SYNCH, PSI-MIDM, and THR)

	CATCH	CHIMERA	SPoCA	PSI-SYNCH	PSI-MIDM	THR	Mean
A [10^{10} km 2]	8.2	10.2	4.9	9.3	11.9	8.8	8.9 ± 2.3
I_{193} [DN]	52.2	58.7	46.4	53.8	65.8	53.0	55.0 ± 6.6

$B_{\text{HMI ADAPT}}$ [G]	-3.1	-2.8	-3.3	-3.1	-2.8	-3.1	-3.0 ± 0.2
B_{GONG} [G]	-2.4	-2.2	-2.5	-2.3	-2.2	-2.3	-2.3 ± 0.1
$B_{\text{GONG ADAPT}}$ [G]	-3.5	-3.0	-3.7	-3.3	-3.0	-3.4	-3.3 ± 0.3
Φ_{MDI} [10^{20} Mx]	-22.5	-27.7	-14.0	-24.7	-32.5	-23.8	-24.2 ± 6.1
Φ_{HMI} [10^{20} Mx]	-17.4	-19.7	-10.9	-19.1	-22.6	-18.2	-18.0 ± 3.9
$\Phi_{\text{HMI ADAPT}}$ [10^{20} Mx]	-25.7	-28.9	-16.2	-28.6	-33.3	-27.1	-26.6 ± 5.7
Φ_{GONG} [10^{20} Mx]	-19.6	-22.2	-12.4	-21.3	-26.0	-20.6	-20.4 ± 4.5
$\Phi_{\text{GONG ADAPT}}$ [10^{20} Mx]	-28.2	-30.9	-17.9	-30.6	-35.3	-29.7	-28.8 ± 5.8

Note. CH parameters: area (A), intensity in 193 Å image data (I_{193}), location of the center of mass (CoM; longitude and latitude), mean magnetic field strength (B), and magnetic flux (Φ), for each magnetic map (MDI, HMI, HMI ADAPT, GONG, and GONG ADAPT).

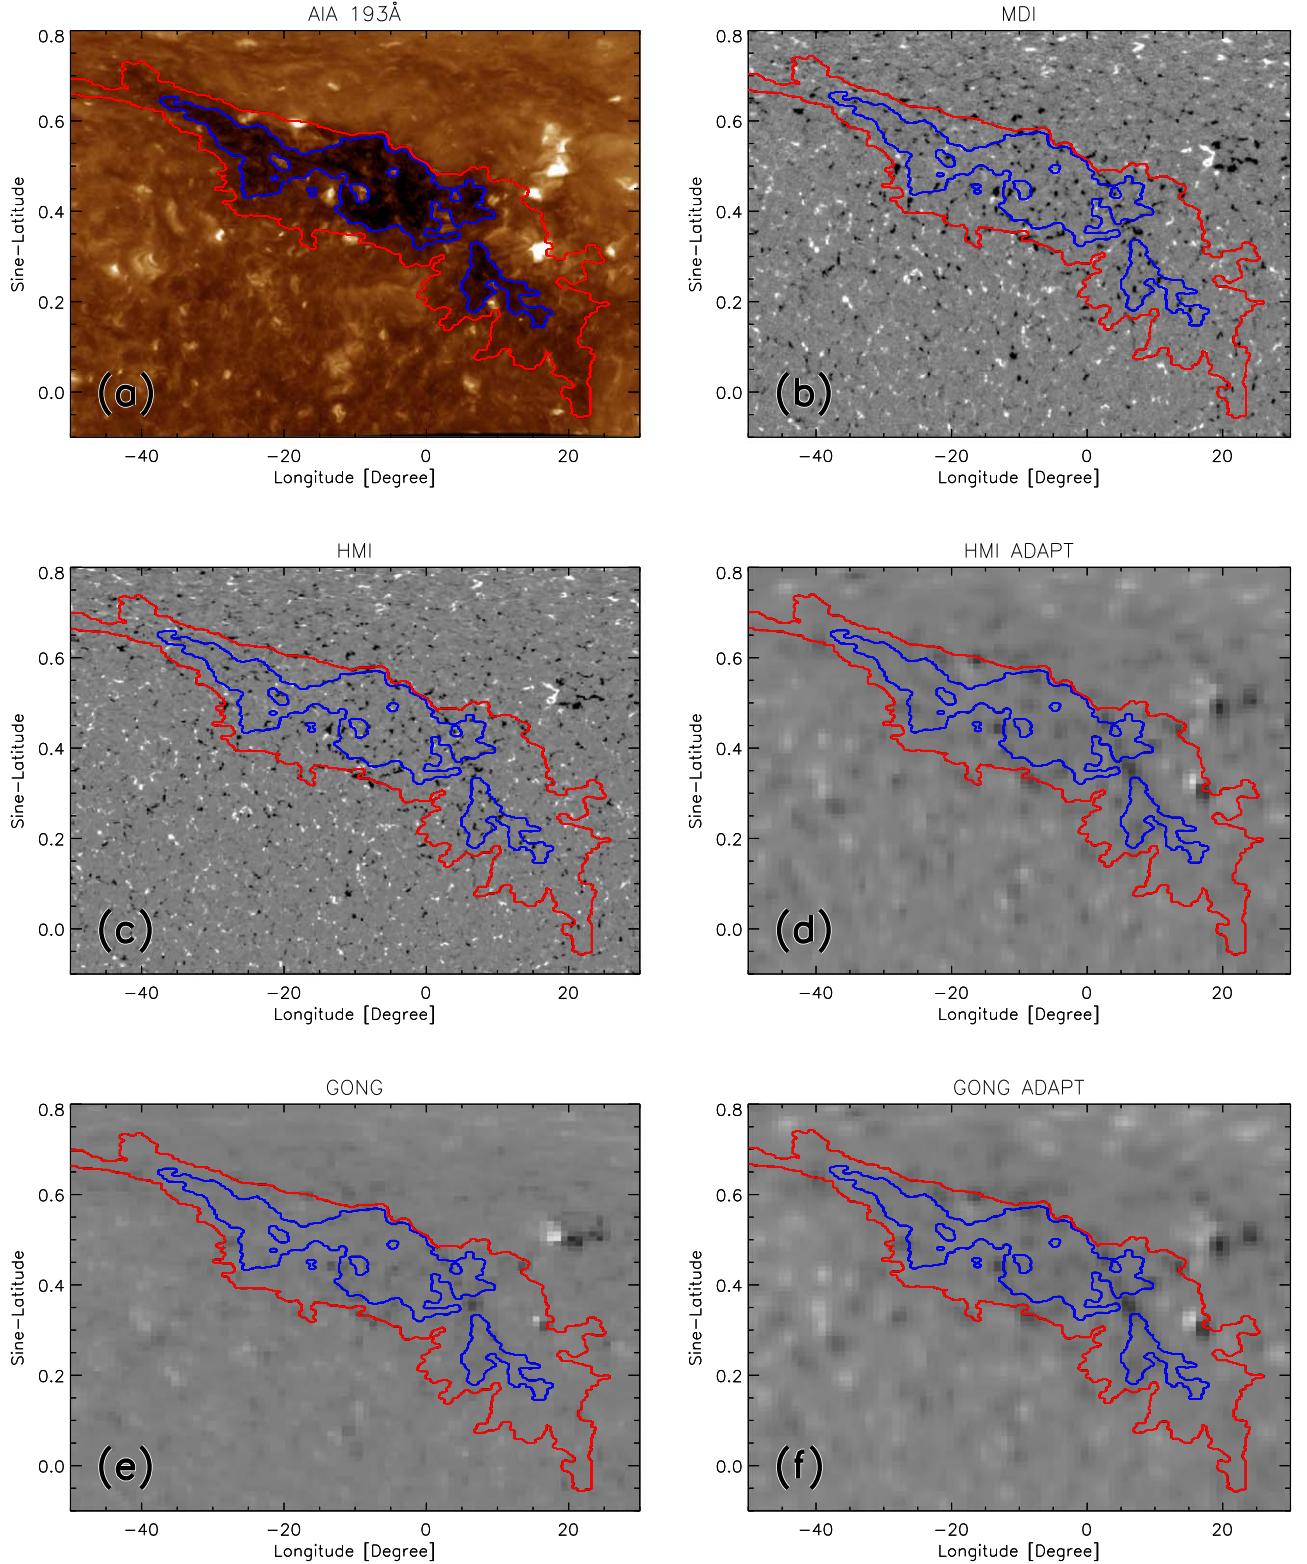

Figure 5. The CH under study (a) shown in EUV, and (b)–(f) in the different photospheric magnetograms. The minimal and maximum CH boundaries are overlaid as blue and red contours, respectively (see Figure 3). The magnetograms are scaled to ± 50 G.

The uncertainty in the open flux from a CH can, in principle, be divided into the uncertainty from the CH extraction ($\sigma_{\Phi_i} \approx 26\%$; see Tables 1 and 2) and the differences/uncertainties between different magnetograms. From this we can conclude that, for a typical extraction method, the uncertainty in the open flux derivation on a well-observed CH is $\sigma_{\Phi} \approx 43\%–46\%$.

3.2. Comparison with Heliospheric Open Flux

Figure 6 shows 1 hr means of ACE solar wind magnetic field and plasma data. For determining the topology of the HMF over CR2101, we used 64 s suprathermal electron and magnetic field data, following the methodology of Owens et al. (2017).

Φ_{GONG} [10^{20} Mx]	−19.6	−18.0	−24.4	−13.2	−21.2	$−19.3 \pm 4.1$
$\Phi_{GONG\ ADAPT}$ [10^{20} Mx]	−28.2	−26.4	−34.4	−18.4	−30.0	$−27.5 \pm 5.9$

Note. CH parameters: area (A), intensity in 193 Å image data (I_{193}), location of the center of mass (CoM; longitude and latitude), mean magnetic field strength (B), and magnetic flux (Φ), for each magnetic map (MDI, HMI, HMI ADAPT, GONG, and GONG ADAPT).

Accounting for inverted HMF and single-point sampling uncertainty, we derive for the heliospheric open solar flux Φ_{SS} in the range $449\text{--}559 \times 10^{20}$ Mx, with a most probable value of 482×10^{20} Mx. Another way of roughly estimating the heliospheric open flux is to use simple averages (an hourly average and a daily average) of the in situ B_R , and then obtain the average of these over the entire rotation. For the hourly averaged data, we obtain an estimate of 626×10^{20} Mx. This is almost certainly an overestimate of the open flux, for the reasons described in Section 2.3. For the daily average, we obtain 464×10^{20} Mx. This likely underestimates the open flux, because for these longer-time averages, B_R is canceled in the vicinity of the heliospheric current sheet as well as in regions with folded flux. These two estimates bracket our most probable value (482×10^{20} Mx) obtained from the more detailed analysis.

Comparison of the open flux in CHs at the Sun with interplanetary measurements requires CH detection for the entire solar surface. The PSI detection techniques, PSI-SYNCH/SYNOPTIC and PSI-MIDM (see Section 2.1), are designed to produce a full-Sun map of EUV and extracted CHs. PSI-SYNCH cannot be used in this capacity for CR2101, because at that time, the combined view of STEREO-EUVI and SDO-AIA did not extend over the entire Sun. PSI-MIDM uses multiple views from AIA, and provides a CH map of the entire Sun over CR2101 shown in Figure 7(a). We also employ PSI-SYNOPTIC, which is similar to PSI-SYNCH, but is built up over a solar rotation in order to obtain a full-Sun view (Figure 7(b)). (We note that due to the $\sim 7^\circ$ tilt of the Sun’s rotation axis toward Earth during this time period, a portion of the south polar region of the Sun was not visible, and we assume that this is open. This lack of visibility likely has a small impact on the estimate of open flux, as described in the Appendix.)

To estimate magnetic flux from the global Sun CH maps, we employ three synoptic maps, namely from HMI, MDI, and GONG, as they are built up over the course of a solar rotation (ADAPT maps are not appropriate as they provide a synchronic representation). Using the two full-Sun maps, PSI-MIDM and PSI-SYNOPTIC, we sum the area of all of the detected open field regions, and we sum the fluxes in each CH individually,

then take the absolute value of each before summing them together. We compute the fluxes in the individual CHs of the full-Sun map in a manner similar to that described in Section 3.1, but we integrated the fluxes on a higher-resolution (1600×3200) latitude–longitude grid, to ensure accuracy in the polar regions. For PSI-MIDM, we obtain an estimate of 84.0×10^{10} km 2 for the open field area and 190×10^{20} Mx for the open flux, using the HMI synoptic map. With the synoptic map, the open flux is 216×10^{20} Mx, and 160×10^{20} Mx for GONG. All of these values are significantly less than the inferred interplanetary flux of 482×10^{20} Mx. The open flux values are even smaller for PSI-SYNOPTIC. With a detected area of 67.5×10^{10} km 2 , the open fluxes are 154×10^{20} Mx (HMI), 174×10^{20} Mx (MDI), and 122×10^{20} Mx (GONG).

When compared to all of the other detection methods and input emission data, PSI-MIDM provides the largest area and flux estimates for our selected CH. Yet the estimate of the solar open flux from all detected CHs in CR2101 with PSI-MIDM is well below the interplanetary flux estimate (by a factor of ≈ 2.2) in the best-case scenario. Our results imply that detected CHs over the entire Sun, regardless of the detection method, contain significantly less flux than is implied by interplanetary observations. However, there may be greater uncertainty in the detection of CHs in other solar regions, particularly at the Sun’s poles. Another way to test CH detection techniques is to apply them to a model where the true answer is known. We describe this approach in the following section.

4. Detection Applied to Simulated Emission

In Section 3, we found that the uncertainty estimates for CH area and open flux for our well-observed CH are far below the amount required to account for the large difference between our coronal and heliospheric open flux estimates for the entire Sun during this time period. However, there is no “ground truth” measurement for the open flux in a CH. There could be systematic errors related to the geometry and properties of CHs for all detection methods. From observational data alone, it is difficult to assess how (i) obscuration by nearby overlying loops, (ii) foreshortening of the emission away from disk center, especially near the poles, and (iii) variation in emission

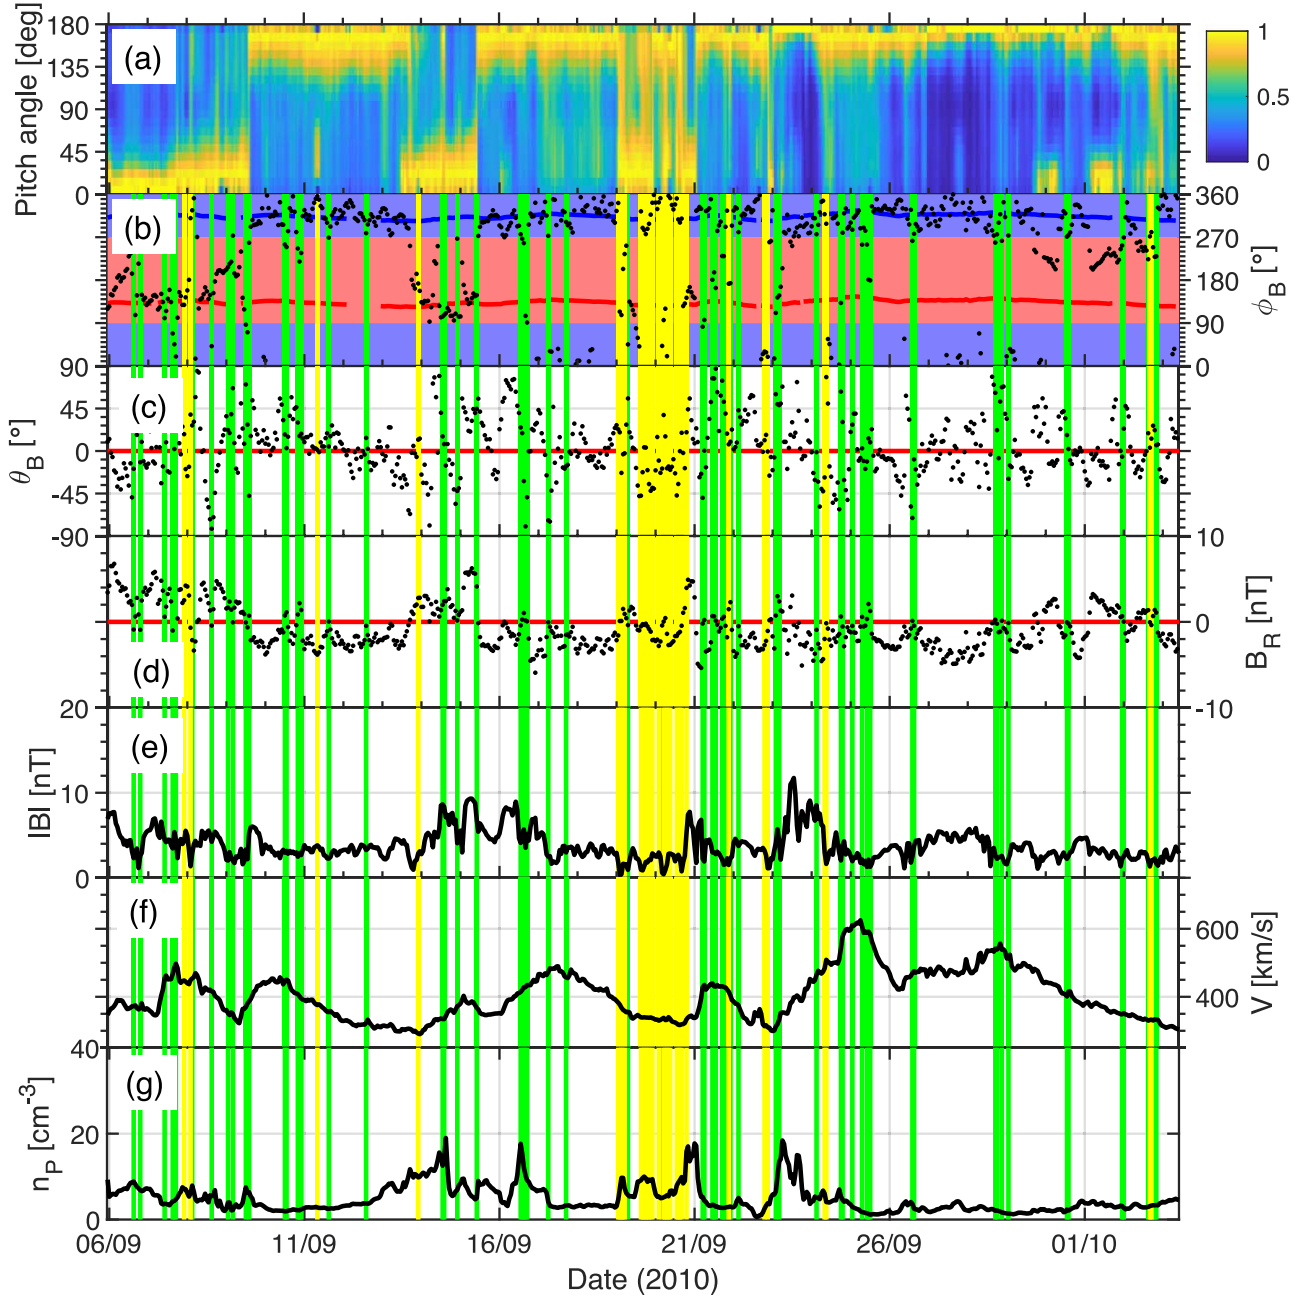

Figure 6. In situ observations during CR2101 from the ACE spacecraft. (a) Pitch angle distribution of 272 eV electrons, with the intensity normalized at each time step. (b) ϕ_B , the HMF angle in the ecliptic plane. Red/blue shaded regions show HMF pointed away/toward the Sun, while the blue/red lines indicate the ideal Parker spiral directions for away/toward polarity HMF. (c) θ_B , the angle of the HMF out of the ecliptic plane. (d) B_R the radial HMF component. (e) $|B|$, the HMF intensity. (f) V , the solar wind speed. (g) n_P , the proton density. intensity over the disk, affect detection of open magnetic flux. To simulate EUV and soft X-ray emission as observed from space, thermodynamic MHD models (e.g., Lionello et al. 2009; Downs et al. 2010, 2013; van der Holst et al. 2014; Mikić et al. 2018; Réville et al. 2020) incorporate a realistic energy equation that accounts for anisotropic thermal conduction, optically thin radiative losses, and coronal heating. To assess how well detection techniques perform when the true answer is known, we developed a thermodynamic MHD simulation of CR2101 using the Magnetohydrodynamic Algorithm outside a Sphere (MAS) code. The solution parameters closely resemble those used for the coronal prediction for the 2017 August 21

total solar eclipse (Mikić et al. 2018); a brief description of these parameters and the computation of simulated emission is described in the Appendix. We describe the features of the simulation relevant to our CH detection tests in the following section.

4.1. Properties of the Simulated Corona

Figure 8 shows some global diagnostics from the model results. Figure 8(a) shows the surface magnetic map (B_r) used as the boundary condition. Red indicates positive (outward) polarity ($+B_r$) and blue indicates negative (inward) polarity

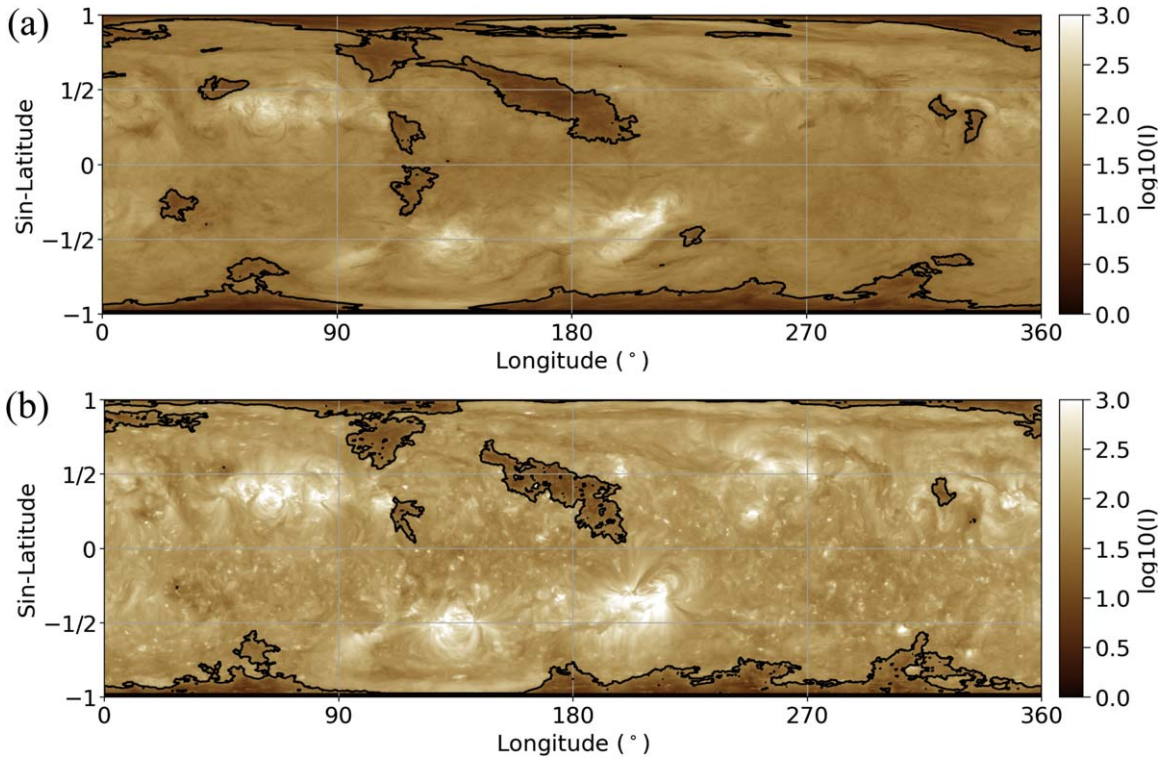

Figure 7. (a) Full-Sun EUV AIA 193 Å map and CH detections using PSI-MIDM. (b) The same as (a) using PSI-SYNOPTIC.

($-B_r$). Figure 8(b) shows a map of the simulated AIA 193 Å emission from the model, with contours of the open field regions (red for $+B_r$, blue for $-B_r$) overlaid on the map. A map of these open/closed field regions is provided in Figure 8(c). These are the “target” areas for our detection methods. Figure 8(d) shows B_r overlaid on the open field map. This is the “true” open magnetic flux in the model, the target that our detection methods seek to extract. Figure 8(b) shows that in the model, in addition to open field regions associated with dark emission and more unipolar magnetic fluxes, there are also dark regions and open flux next to active regions. This is in contrast to the observations (Figure 7), where this dark emission is less apparent near the active regions, but may be obscured by bright active region loops. Figures 8(e)–(h) show full-Sun CH detections and are described in Section 4.2.

To create simulated EUV images, we convolve the plasma density and temperature from the model with the SDO/AIA instrument response functions. Synthetic images are created by integrating the 3D volumetric emissivity along the LOS from a given viewpoint (see the Appendix for more details). The EUV map in Figure 8(b) was constructed by integrating along radial LOS; Linker et al. (2017) described a detection test with PSI-SYNOPTIC on a similar EUV map. While this comparison yielded useful insights, in general, such a map is more favorable for detection than real images from spacecraft instruments. This is especially true in the polar regions, where images obtained from ecliptic-based instruments suffer from considerable foreshortening.

To provide more realistic conditions to test CH detection techniques, we created a sequence of synthetic emission images in multiple wavelengths from the MHD simulation as observed from the vantage point of SDO/AIA. Figure 9 shows an observational comparison for the date and time of our selected CH in the different SDO/AIA filters. The comparison shows

that the model has roughly captured all prominent features of the corona at this time, including the approximate location and size of active regions and CHs. However, the simulated CHs are generally darker and more uniform than in real observations. This is in part caused by the smoothness of the boundary map (Figure 8(a)), which does not include the mixture of small-scale parasitic polarities that are prevalent at high resolution (compare with Figure 5). These small-scale structures likely contribute to the bright points of emission that tend to “break up” CHs. This effect is likely to be especially prominent in the 171 Å line, where small-scale heating processes may dominate the lower temperature plasma and exhibit more structure at smaller scale heights. The simulated active regions also tend to be less structured than the observed ones. Conversely, some of the simulated active region emission is over-bright compared to the observations, and this may lead to more obscuration than in observed structures. These less realistic attributes of the simulated corona are related to resolution/computational cost and properties of the coronal heating model. Further details are provided in the Appendix.

4.2. Testing Detection Methods

We applied our CH detection methods to the synthetic AIA images, which we created from the simulation, each method using its own processing methodology as if this was a real observation. The results are shown in Figure 10. The simulated emission in the selected CH (top left) shows less structure than the real CH. The contours of the true open field regions (shown in cyan) reveal that the magnetic structure in the simulation is more complex. Two closed field regions (cyan circles) are present within the main body of the CH, but these features are not revealed in emission (possible reasons for this are discussed in Section 5.3 and the Appendix). Contours of the different detection schemes (Figure 10, bottom left) all incorporate these regions as open. The

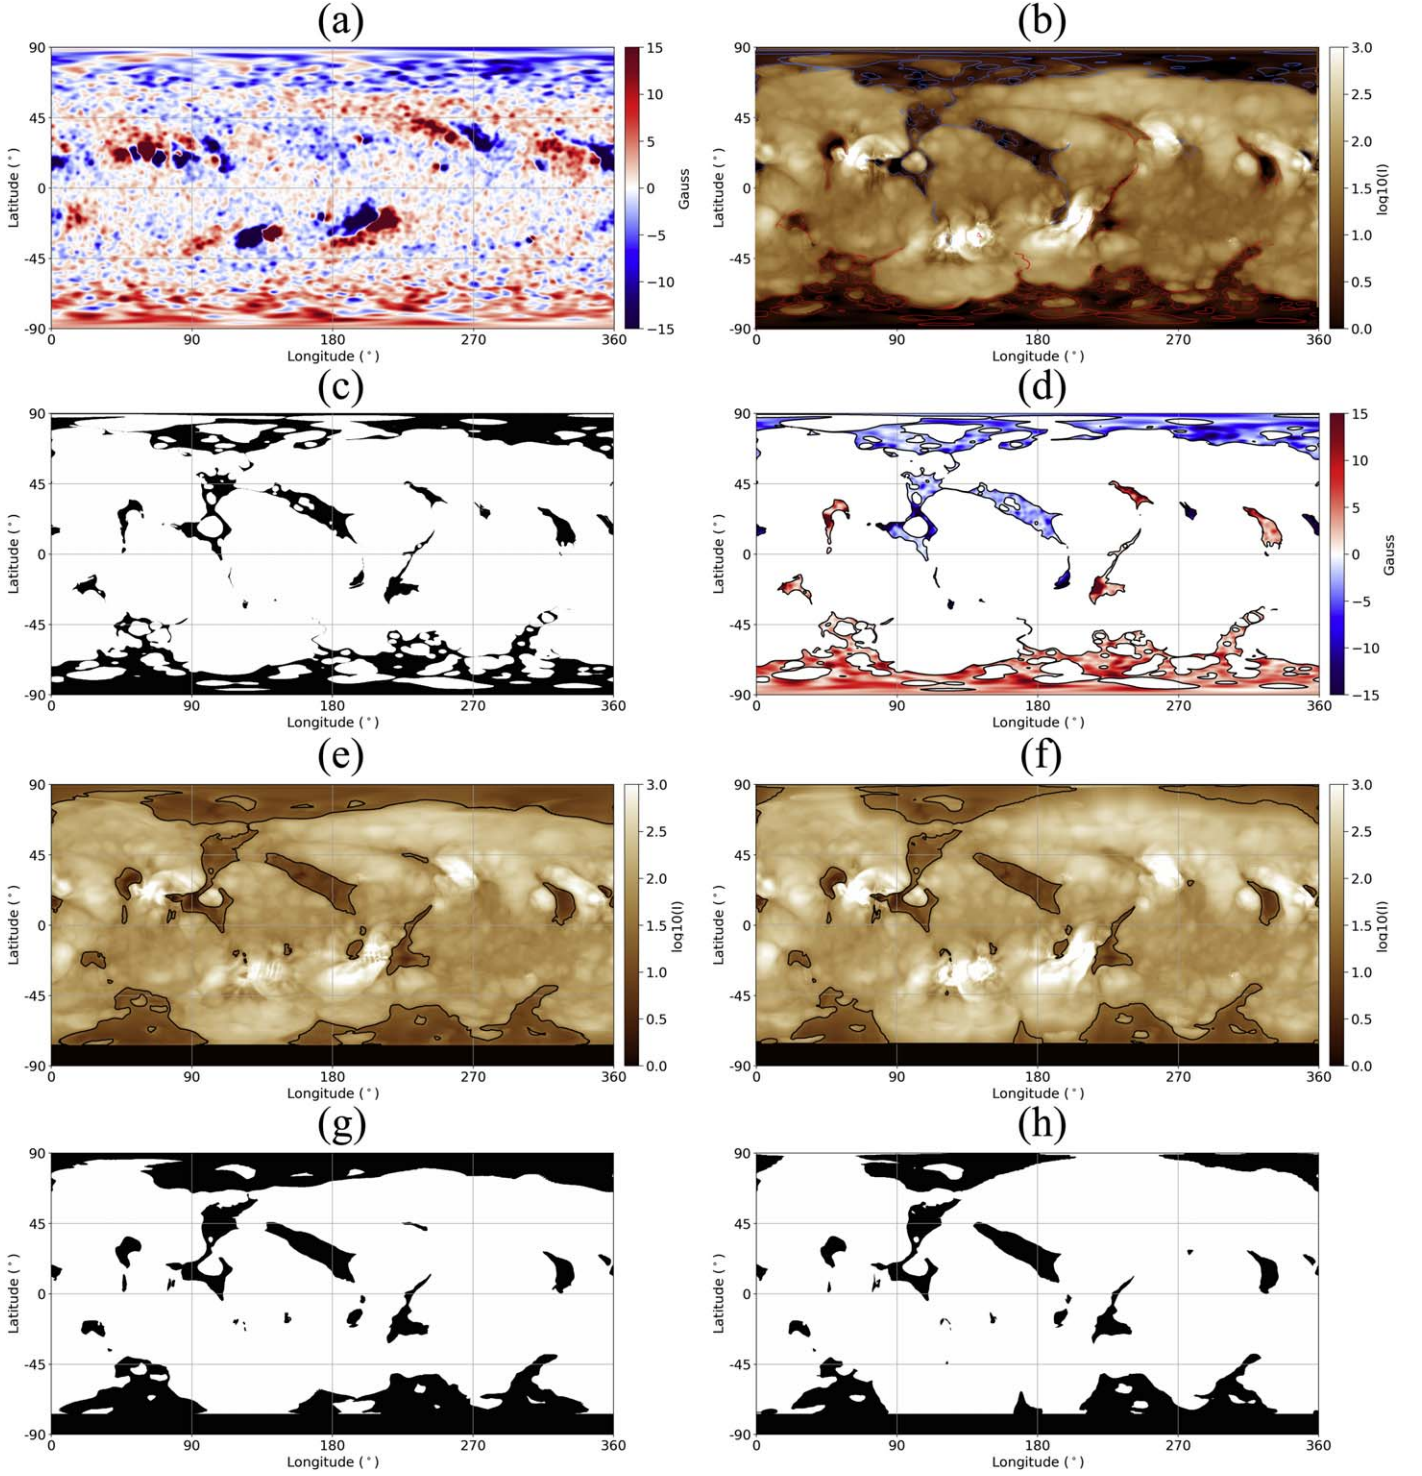

Figure 8. Results from a thermodynamic MHD simulation of the solar corona for CR2101. (a) Map of B_r at the solar surface from an HMI synoptic map, the boundary condition for the calculation. (b) Map of simulated AIA 193 Å emission from the model (see the text). The open field regions of the model, calculated by tracing field lines, are overlaid on the EUV map as colored contours. Red colors indicate positive (outward) polarity, and blue colors indicate negative (inward) polarity. (c) Map of the open (black) closed (white) field regions of the model. (d) Map of B_r overlaid on the open field map. This is the open magnetic flux in the model. (e) Map of simulated AIA 193 Å emission, assembled using the PSI-MIDM detection scheme. The detected open regions are overlaid as black contours. (f) The same as (e), but for PSI-SYNOPTIC. (g/h) CHs in the model (black) detected by PSI-MIDM/PSI-SYNOPTIC—these are the same as the black contours in (e/f).

CATCH, SPoCA, and PSI-MIDM extracted boundaries are similar, with CHIMERA and THR providing somewhat larger boundaries. The minimal and maximal boundaries, constructed by overlaying the five individual boundaries, along with the true open field boundaries, are shown in the top right of Figure 10. A

stacked map of the detections is shown in the bottom right. To estimate the magnetic fluxes in the detections, we assume the values in the boundary map that was used in the simulation (Figure 8(a)), i.e., we assume there is no error in magnetic flux incorporated in the detections.

Figure 9. Comparison of observed and simulation AIA emission images on 2010 September 19, at 17:59 UT. Top row: observed AIA emission in 171 Å (left), 193 Å (middle), and 211 Å (right). Bottom row: Simulated emission in the same wavelengths.

The numerical results for the detections, along with the true values, are provided in Table 3. The average detected area of the CH ($11.5 \times 10^{10} \text{ km}^2$) is considerably larger than the true area ($7.4 \times 10^{10} \text{ km}^2$), but the average strength of B_r in the detected areas is smaller in absolute value (-2.1 G) than the true value (-3.1 G). This occurs because regions that were misidentified as open by the detection methods had primarily mixed polarity magnetic flux, lowering the magnitude of the average value. The resulting average estimate for the open magnetic flux from this CH is $24.2 \times 10^{20} \text{ Mx}$ for all of the detections, only about 7% above the true value. All but one of the methods overestimated the open magnetic flux in the CH. The reasons for this are discussed further in Section 5.3, but probably occur because this is a relatively simple CH, situated away from any strong active regions. We will see this is generally not the case when detecting open magnetic flux from all CHs (i.e., over the full Sun).

To investigate how well CH detection methods can estimate the total open magnetic flux, we again employ the PSI-MIDM and PSI-SYNOPTIC algorithms, as we did for the observed CHs of CR2101. Figures 8(e) and (f) show the global EUV maps built up with these detection algorithms. The dark band near the southern pole in these images occurs because of the tilt of the Sun’s rotational axis during this time period. As in the case of the real observations (Section 3.2), we assume this region to be

completely open. This turns out to only slightly increase the estimated open flux (see the Appendix). Figures 8(g) and (h) show the detected CHs using these two methods (same as the black contours in (e) and (f)). Comparison with Figures 8(c) and (d) shows that the algorithms generally detect most of the true open field regions. However, the CH structure identified by the methods is generally simplified compared to the true open fields, and areas are overestimated in a number of regions, including the poles. Some smaller CHs are missed or not fully captured, and as these areas are associated with active regions, they contain a disproportionate amount of open flux. Overall, PSI-MIDM does a better job of identifying open flux than PSI-SYNOPTIC, especially in the polar regions (e.g., longitudes 200° – 260° in the north and 150° – 210° in the south), where it correctly identifies regions that are obscured from PSI-SYNOPTIC. However, PSI-MIDM overestimates the open field area relative to PSI-SYNOPTIC in other regions, such as near the southern pole at longitudes 20° – 100° .

For the PSI-MIDM method, we find that the total Sun detected CH area is $83.91 \times 10^{10} \text{ km}^2$ and the detected open flux is $285 \times 10^{20} \text{ Mx}$. The PSI-SYNOPTIC method finds a detected CH area of $67.98 \times 10^{10} \text{ km}^2$ and detected open flux of $240 \times 10^{20} \text{ Mx}$. The true open field area was $60.41 \times 10^{10} \text{ km}^2$ and true open flux was $386 \times 10^{20} \text{ Mx}$. Both methods overestimate the total areas of all CHs (38.9% by PSI-MIDM

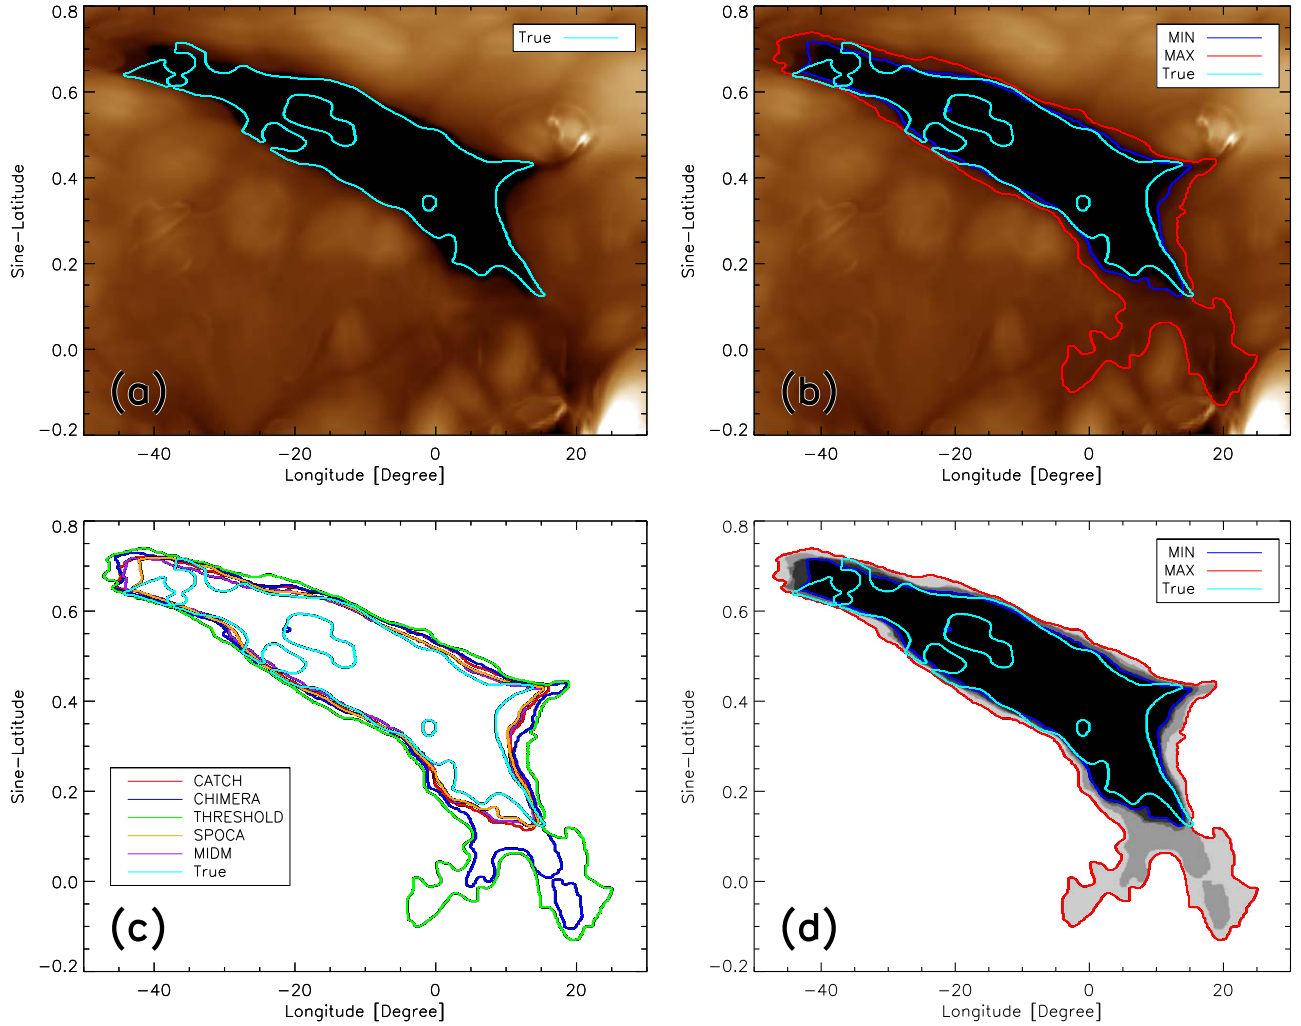

Figure 10. CH boundaries extracted using different methods applied to synthetic AIA/SDO emission, derived from the MHD model. (a) The synthetic AIA/SDO 193 Å filtergram, with the contours of the true open field area shown in cyan. (b) The same filtergram as (a), overlaid with true open field (cyan), the minimum (dark blue) and maximum (red) boundary constructed by overlaying the five individual boundaries. (c) The different boundaries extracted by the means of CATCH (from AIA/SDO 193 Å), CHIMERA (from AIA/SDO 171/193/211 Å), thresholding (with 35% of the median solar disk intensity), SPOCA (AIA 193 Å), and MIDM (AIA 193 Å multiple images), along with the true open field. (d) A stacked map of the five binary extractions (where darker pixels represent an agreement of more extractions).

and 12.5% by PSI-SYNOPTIC) but underestimate the total open flux (PSI-MIDM captures 73.8% of the flux and PSI-SYNOPTIC captures 62.1%). These underestimates are discussed further in the following section.

5. Discussion

5.1. CH Detection on a Well-observed CH

Our comparison of detection methods for the area of the observed CH reveals a standard deviation of $\sigma_A \approx 26\%$ from the mean value, which we estimate to be the approximate uncertainty in the methods. The variability in the magnetic fluxes from different magnetic field maps raises this uncertainty to $\sigma_A \approx 43\%$ – 46% . These uncertainties are for a particularly well-observed low-latitude CH, with no large active regions closely adjacent. There could be more variability (and therefore more uncertainty) in detections performed on more complex CHs.

In the methods comparison performed on the simulated CH, the standard deviation for the detected areas was similar to the observed case, about 21%. However, the mean of these values ($11.5 \times 10^{10} \text{ km}^2$) was actually 36% greater than the true value

($7.4 \times 10^{10} \text{ km}^2$). All but one of the methods overestimated the open flux in the simulated CH, but the standard deviation in the open flux was much smaller (8.4%) than for areas. The actual error of the mean open flux compared with the true value was even less (7%). This reflects the fact that if mixed polarity regions are misidentified as open, they do not contribute as much to the flux estimate because the opposite polarities cancel in the integration.

While the standard deviation for the detected areas provides a measure of the uncertainty of the different methods, this does not necessarily imply that the mean value is the best estimate of the true value. For the detections performed on the simulated CH (Table 3), SPOCA and PSI-MIDM provide values that were smaller and further from the mean value (compared to the other three methods) for both the detected area and open flux, but these turned out to be closer to the true values for this case.

5.2. Detection of the Global Open Flux

Tables 4 and 5 summarize our full-Sun detections for both observations and the model. The open flux inferred from

Table 3
Extracted CH Parameters

Table 5
Areas and Open Fluxes Derived from Full-Sun Detections of Simulated CHs for CR2101

Method	Area (10^{10} km 2)	Open Flux (10^{20} Mx) (B_r at 1 au)	True Area	True Flux
MIDM	83.9	285 (1.01 nT)	60.4	386 (1.37 nT)
SYNOPTIC	68.0	240 (0.85 nT)		

heliospheric observations for this time period was in the range $449\text{--}559 \times 10^{20}$ Mx, with a most probable value of 482×10^{20} Mx, corresponding to $B_R = 1.71$ nT at 1 au. The full-Sun detections, regardless of the magnetic map used, greatly underestimate these values. The highest estimate (0.77 nT) comes from PSI-MIDM with the MDI synoptic magnetic field map, and this detection was well above the mean value for the detections on the selected individual CH. The uncertainties we estimated for the area and open flux of the selected well-defined CH are likely less than for full-Sun detections, where factors such as obscuration and viewing geometry play a larger role. Our full-Sun detections on the model corona at least partially account for these aspects, and indeed show that the methods, while overestimating the CH area, actually underestimate the global open flux (e.g., the true open flux is 35% greater than the PSI-MIDM estimate). However, even applying this factor to the PSI-MIDM full-Sun detection of the observations leaves us well short of the estimated heliospheric interplanetary flux.

5.3. Overestimates of Open Flux in Individual CHs

There are two primary sources to the overestimate of the area and open flux on the individual, simulated CH. The first can be seen by comparing the true open field contour (cyan) in Figure 10 with the simulated emission and all of the extracted CH boundaries in the figure. Pockets of closed field appear dark in emission in the figure, and are indistinguishable from open field to

the detection methods. This may be less likely to occur on the real Sun, where these small-scale loops may appear brighter in emission than they do in the model. The absence of emission here may be due to deficiencies in the coronal heating model for small-scale loops (see the Appendix).

The second source of overestimation occurs because, as implemented here, the methods do not account for the coronal height at which the bulk of the emission begins to form in the EUV lines used in the detection (estimated to be about $1.01 R_\odot$ for 193 and 195 Å emission; Caplan et al. 2016, see Section 4.2 and Figure 18). In Figure 10(b), even the minimal boundary area contour (blue) is larger than and almost completely envelopes the true open field contour (cyan). This occurs because the magnetic field expands with height and the CH has a larger area at the height of detection than at its magnetic source in the photosphere. Simply projecting the CH area downward on the photosphere captures a larger area than the actual magnetic source. In the model, the plasma at chromospheric temperature is artificially thick, and the 193 Å emission forms at $1.02 R_\odot$. Calculating the area of the true open field at this height, we find that this rises to 9.3×10^{10} km 2 , much closer to the detected areas (especially for SPoCA and PSI-MIDM). This result suggests that CH detection methods may be able to improve the estimates of the open magnetic flux by using a potential field model to extrapolate B_r to the height at which the emission forms, slightly lowering the flux estimate.

5.4. Underestimates of Total Open Flux

The full-Sun detections, when applied to the model corona, underestimate the total open flux, with PSI-MIDM accounting for 73.7% of the flux and PSI-SYNOPTIC accounting for 62.0%. The reason for these underestimates can be seen by comparing the true open field regions (Figures 8(c) and (d)) with the detections (Figures 8(g) and (h)). There are several smaller-scale open field regions that are under-detected or completely missed in the extracted CH boundaries. These often are in the proximity of active regions, which contain significant amounts of magnetic flux. For example, the northern active region near $\sim 40^\circ$ latitude and $\sim 260^\circ$ longitude (panels (a), (b), (e), and (f) of Figure 8) inhibits the detection of the adjacent open flux regions at longitudes $\sim 240^\circ$ and $\sim 280^\circ$ (Figures 8(c) and (d)). These CHs account for 6% of the total open flux in the model, but they are almost completely missed in the extracted CH boundaries for both methods (panels (g) and (h) of Figure 8). Linker et al. (2017) and Caplan et al. (2019) also found that open flux was underestimated by these detection methods for the same reasons.

5.5. Implications for the Open Flux Problem

Our comparisons of detection methods on our selected CH, for both the observed and simulated cases, show reasonable agreement between the methods. Uncertainty from the different magnetic map products contributes as much to the variability as the detections themselves. The average error in the detected open flux for the simulated CH was relatively small (7%). The full-Sun detections for the observed case all greatly underestimated the open flux deduced from in situ measurements, with the largest estimate still a factor of 2.2 smaller than the interplanetary value. The schemes also underestimated the open flux for the model corona. However, the model's true open flux was only 35% greater than the estimate from the PSI-MIDM detection.

The under-detection of open flux within the traditionally described CH areas may well contribute to the open flux problem; however, it seems unlikely that it is the only reason and, therefore, cannot resolve it.

We note that the open flux in the simulated corona was relatively close ($\approx 80\%$) to the in situ value. However, the open field regions in the model at mid-latitudes and near active regions are larger and more obvious than in the observations. If regions like this exist on the real Sun and contribute to the open flux, they would have to be considerably more obscured than occurs in the model.

One possible resolution to the open flux problem is that the under-detection of open flux (e.g., near active regions), in combination with systematic underestimates of magnetic flux by magnetographs (either everywhere on the Sun, or just at the poles), could account for the missing open flux. In this regard, the behavior of CHs at the poles could be especially important, and our present observational views of the Sun's poles limit our ability to resolve this question. The latter part of the Solar Orbiter mission, when the spacecraft will reach latitudes of $\sim 30^\circ$, may yield clues to the importance of the polar contribution. Ultimately, a mission that fully images the Sun's poles (such as the Solaris mission; Hassler et al. 2019, 2020) can resolve the contribution of the Sun's polar regions to the open flux.

A second possibility is that a significant portion of the open flux is rooted at the Sun, but continually undergoes interchange reconnection, and the mixture of open and closed field lines are not obviously dark in emission. While interchange reconnection has been advocated as an explanation for the origin of the slow solar wind (e.g., Abbo et al. 2016, and references therein), it is not clear what emission properties the plasma on these field lines would possess. Therefore, with the present state of the theories/models, it is difficult to either completely confirm or falsify this idea from observations alone. An advanced model that simulates the time-dependent evolution of the corona and demonstrates the observed emission properties would seem to be necessary to progress beyond the present qualitative arguments.

A third possibility is that the disparity between observed coronal and heliospheric open flux is not related to solar observations, but to the behavior of the interplanetary magnetic field. The discovery of long intervals of “switchbacks” in the interplanetary magnetic field from PSP (Bale et al. 2019; Kasper et al. 2019) suggests that folded flux could be more ubiquitous than previously thought, and lead to increases in the magnitude of B_R measured in situ at increasing distance (i.e., 1 au) from the Sun (Macneil et al. 2020). However, comparison of PFSS and MHD models with PSP observations (Badman et al. 2021; Riley et al. 2021) suggests that the models significantly underestimate the field strength even at the perihelion distances that PSP has reached thus far, though more detailed accounting for switchbacks may be necessary. Large amounts of disconnected flux in the heliosphere could also account for the missing open flux. This has generally been considered unlikely (Crooker & Pagel 2008), but recent PSP observations of reconnection in the heliospheric current sheet (Lavraud et al. 2020; Phan et al. 2021) indicate that this process appears to be more prevalent than previously thought.

6. Summary

We have investigated CH detection techniques to elucidate the uncertainty in characterizing CH area and open flux from observational EUV data. Starting from a well-observed, near-disk center CH, we applied six different detection methods to deduce the area and open flux. We also applied a single method to five different EUV filtergrams for this CH. Open flux was calculated for all of the detections using five different magnetic maps. Using the standard deviation as a measure of the uncertainty, we find that the uncertainty in the estimate of open flux for this particular CH was $\approx 26\%$. When including the variability in the different magnetic data sources, this uncertainty rises to 43%–46%. We used two of the methods to characterize the area and open flux for all CHs during CR2101. We find that the open flux is greatly underestimated compared to the value inferred from in situ measurements, by a factor of 2.2–4. As there is no “ground truth” measurement of open flux in CHs, we tested our detection techniques on simulated emission images from a thermodynamic MHD model of the solar corona for this time period, where the true values of the model are known. The variability in the detected area of the simulated CH is similar to the observed case. The methods generally overestimate the area and open flux in the simulated CH, but the average error in the flux is only about 7%. The full-Sun detections on the simulated corona underestimate the model open flux (by 35% for PSI-MIDM), but this factor is well below what is needed to account for the missing flux in the

observations. Our results imply that under-detection of open flux in what are traditionally considered to be coronal holes likely contributes to the open flux problem, but is unlikely to resolve it.

We thank the International Space Science Institute (ISSI, Bern) for the generous support of the ISSI team “Magnetic open flux and solar wind structuring in interplanetary space” (2019–2021). J.A.L., R.M.C., and C.D. were supported by the NASA Heliophysics Guest Investigator program (grants NNX17AB78G & 80NSSC19K0273), the NASA HSR program (grant 80NSSC18K0101 & 80NSSC18K1129), AFOSR (contract # FA9550-15-C-0001), the NSF PREEVENTS program (grant ICER1854790), and the STEREO SECCHI contract to NRL (under subcontract N00173-19-C-2003 to PSI). Computational resources were provided by NASA’s NAS (Pleiades) and NSF’s XSEDE (TACC & SDSC). Appendix Thermodynamic MHD Model

We developed an MHD simulation of CR2101 using the Magnetohydrodynamic Algorithm outside a Sphere (MAS) code. The method of solution, including the boundary conditions, has been described previously (e.g., Mikić & Linker 1994; Lionello et al. 1998, 2009; Linker et al. 1999). The solution parameters closely resemble those used for the coronal prediction for the 2017 August 21 total solar eclipse (Mikić et al. 2018), including a wave-turbulence-driven (WTD) model of coronal heating (Downs et al. 2016). The simulation utilized a $288 \times 327 \times 699$ nonuniform r , θ , ϕ mesh, with the smallest radial cells of $\Delta r = 0.00043R_\odot$ (≈ 300 km) near the solar surface and $\Delta r = 0.83R_\odot$ at the outer boundary of $30R_\odot$. For the co-latitude mesh, $\Delta\theta = 0^\circ.51$ near the equator and $0^\circ.86$ near the poles, and for the longitudinal mesh, $\Delta\phi = 0^\circ.51$ was uniform. The boundary condition was derived from the HMI LOS synoptic map for CR2101, available at http://jsoc.stanford.edu/HMI/LOS_Synoptic_charts.html. As in Mikić et al. (2018), we multiplied the HMI map by a factor of 1.4 to account for the difference between HMI and MDI data (Liu et al. 2012), which

was previously used to calibrate the heat flux in the model. We divide out this 1.4 factor prior to computing the true and estimated magnetic fluxes in the detected CHs described in Section 4.2, to make these more comparable with the values derived from observations.

The instrument response functions were developed using the AIA v6 calibration, the CHIANTI 8.0.2 database (Del Zanna et al. 2015) and the CHIANTI hybrid abundances (Fludra & Schmelz 1999), based off of Schmelz et al. (2012). Synthetic images are created by integrating the 3D volumetric emissivity along the LOS from a given viewpoint. The EUV map in Figure 8(b) was constructed by integrating along radial LOSs; Linker et al. (2017) described a detection test with PSI-SYNOPTIC on a similar EUV map. While this comparison yielded useful insights, in general, such a map is more favorable for detection than real images from spacecraft instruments. While obscuration of CHs from bright loops can still occur, this LOS occurs only at disk center. Away from disk center (especially at higher latitudes) more obscuration may occur, and polar regions are especially foreshortened.

To test CH detection techniques under more realistic conditions, with a data set more akin to those actually produced by AIA, we created a sequence of synthetic emission images in multiple wavelengths from the MHD simulation as observed from the vantage point of SDO/AIA. The B0 angle (i.e., the heliographic latitude of the central point of the solar disk) of the Sun is included in the geometry. A set of images was created approximately every six hours, for a total of 111 image sets. As described in Section 4.1, smoothing of the magnetic map reduces the presence of small-scale, mixed polarities, and these provide important contributions to the complexity of real emission images. The amount of smoothing of the map is in turn determined by the available resolution for the MHD simulation, which strongly influences the computational cost. A second simplification of the model is the attempt to describe all of coronal heating with the simplified WTD description (for details, see Downs et al. 2016). The origin of coronal heating is, of course, controversial. The WTD mechanism, even if proven generally valid, may not be applicable to heating at all coronal scales, as small-scale heating may be dominated by other mechanisms. This may be more important for the 171 Å line, which has contributions from lower temperature plasma and exhibits more structure at smaller scale heights. This effect can only be explored by performing much higher-resolution simulations than the one we employ here. Furthermore, to capture the solar atmosphere’s thin transition region while still modeling the vast scales of the solar corona, the simulation artificially broadens the transition region by modifying the thermal conduction and radiative losses at lower temperatures. This approach (Lionello et al. 2009; Mikić et al. 2013) has been shown to accurately reproduce coronal solutions at higher temperatures (for this case, $>400,000$ K) but can significantly modify the density (and thus emission) at lower temperatures. This effect is again most likely to influence simulated 171 Å emission. Improved accuracy at lower temperatures can be provided at the cost of smaller cells in the transition region.

Despite the aforementioned shortcomings, the simulated emission images still provide a robust test of CH detection techniques, including obscuration by overlying structures, orders-of-magnitude differences in emission intensity between different portions of the solar disk, and realistic geometry. As with the observations, a small portion of the southern pole is

not visible from our simulated viewpoint, due to the tilt of the Sun's rotation axis toward Earth during this time period. In our full-Sun detection tests, we assumed this region was open, the same as we did in the observed case. This assumption can only increase the open field area and flux estimate. It turns out to contribute about 3.8% to the overestimate of the total CH area for the detection methods, and less than 1% to the open flux estimate, when compared to the true values of the model. Therefore, we expect this assumption to also have minimal impact on the full-Sun estimates for the observed case.
